## Abstract

In spoken language applications such as conversation systems where not only the speech waveforms but also the content of the speech (the text) need to be generated automatically, a Concept-to-Speech (CTS) system is needed. In this paper, we address several issues on designing a speech corpus to facilitate an instance-based integrated CTS platform. Both the instance-based CTS generation approach and the corpus design process are new topics and they have not been addressed systematically in previous researches.

# Designing a Speech Corpus for Instance-based Spoken Language Generation

Paper-ID: P0293

## Abstract

In spoken language applications such as conversation systems where not only the speech waveforms but also the content of the speech (the text) need to be generated automatically, a Concept-to-Speech (CTS) system is needed. In this paper, we address several issues on designing a speech corpus to facilitate an instance-based integrated CTS platform. Both the instance-based CTS generation approach and the corpus design process are new topics and they have not been addressed systematically in previous researches.

## 1 Introduction

Instance-based (concatenation-based) Text-to-Speech (TTS) synthesis in which pre-recorded speech segments are selected and reused to generate new utterances becomes increasingly popular. So far, the best TTS systems available on the market are instance-based. In addition, instance-based approaches are particularly effective for domain-specific applications in which large phrases, sometimes even entire utterances can be reused for both waveform and prosody generation (Donovan, 1999, Pan, 2002).

In many spoken language applications such as conversation systems where not only the speech waveforms but also the content of a speech (the text) need to be automatically generated, a TTS system is not sufficient because it requires online text as input. Instead, we need a Concept-to-Speech (CTS) system in which speech is generated directly from semantic representations. There are two separated stages in a traditional CTS framework, natural language generation (NLG), which constructs the content and produces grammatical text, and TTS, which synthesizes speech from the text. In this uncoupled framework, a TTS

has to infer everything such as syntactic and discourse structures from text, even though most information is available during NLG. Since not only pre-recorded speech segments but also sentence structures and wording can be learned and reused based on pre-stored corpus instances (Varges 2001), we can extend the same framework to cover the entire CTS process. Moreover, since instance-based approaches work especially well in domain-specific applications, and almost all the existing CTS applications are domain-specific, we expect this approach to be effective for most CTS applications. Overall, instance-based learning provides an integrated platform for both text and speech generation. It allows the decisions in text generation directly affect speech synthesis, which is difficult to achieve in a traditional CTS systems. Except for some template-based approaches, our work is the first on integrated CTS generation.

To facilitate an instance-based CTS framework, we create a speech corpus from which our system learns both text generation and speech synthesis. Since all the linguistic and speech knowledge used by the system is encoded in the corpus, what is available in the corpus and how information is represented in the corpus have direct impact on the capability of a CTS generator. Until now, research issues on corpus design for CTS generation have not been systematically addressed.

Our work is part of a larger effort in developing multimodal conversation systems. To aid users in their information-seeking process, we are building an intelligent infrastructure, called Responsive Information Architect (RIA), which can engage users in a full-fledged multimodal conversation. A user interacts with RIA using multiple input channels, such as speech and gesture. Similarly, RIA acts/reacts to a user's request/response with automatically generated speech and graphics presentations. Currently, RIA is embodied in a testbed, called Real Hunter, a real-estate

application for helping users find residential properties. As part of the effort, we are building SEGUE (Spoken English Generation Using Examples), the CTS generator in RIA. SEGUE employs an instance-based framework to systematically generate both text and speech.

The rest of the paper is organized into three sections. We first describe the principles and an algorithm used in collecting and generating corpus instances. Then we describe the annotation schemas represented in XML format, which capture typical language and speech features. Finally, we briefly discuss how this corpus is used in CTS generation.

## 2 Designing Corpus Scripts

### 2.1 Design Principles

The basic principle is to create a corpus to cover words and sentences that are most likely to be reused. In addition, a corpus should also cover sufficient variations to support flexible generation. Thus, each instance in a corpus should fulfill at least one of the following purposes: semantic coverage, syntactic coverage, prosodic coverage and word coverage.

**Semantic coverage** In the corpus, there should be at least one instance covering each domain concept and relation. For example, in RIA, we cover all the concepts and relations represented in RIA's domain ontology.

**Syntactic coverage** The corpus should cover as many syntactic variations as possible, even though full syntactic coverage is not possible. Syntactic paraphrases not only create less repetitive and livelier sentences, but also provide rich substructures (such as noun or adjective phrases) to be reused in constructing new sentences. Moreover, when corpus instances are read and recorded to create a speech corpus, syntactic paraphrasing often results in prosodic variations because changes in word position or syntactic function frequently lead to prosodic changes.

**Prosodic coverage** A corpus should cover as many prosodic variations of the same words or phrases as possible because during speech synthesis, a CTS system looks for prosodically appropriate speech segments to reuse.

**Word coverage** A corpus should cover as many domain words as possible even though

sometimes, full word coverage is hard to achieve.

In the following, we focus on how to collect corpus instances to satisfy these requirements.

### 2.2 Resources

When we prepare scripts to be read during record, the scripts should be close to the utterances to be generated. Since RIA responses to a user with automatically generated speech and graphics, ideally all the corpus scripts should come from a multimodal conversation corpus. In addition, the corpus should also cover the real estate domain. Since there is no single corpus known to us that satisfies all the requirements, our corpus is based on several different resources.

**Online real estate web sites.** There are a large amount of real estate data available online. Thus, online web sites are RIA's main source of information. However, they contain primarily written texts and sometimes, the content may not be appropriate for speaking. For example, the term EIK, which is common in written text, is rarely used in speech.

**Monologue Transcriptions** To make the corpus more spoken, we gather speech transcripts from real estate TV programs. Thanks to auto caption, we can easily accumulate many hours of speech transcripts. However, since the content of the TV programs is quite different from that of our application, only a small fraction of the data is useful.

**Conversation Transcriptions** We also collect both unimodal and multimodal conversation transcripts for RIA. So far, we have transcripts from our initiate user study. We also add multimodal conversation scripts from both RIA's test runs and mock-up demos. Content-wise, these scripts are close to SEGUE's target outputs. However, sometimes, they are not totally natural.

Thus, our *initial corpus* consists of scripts from several resources. In the following, we describe how to transform such an *initial corpus* into one that is compatible with the design principles.

### 2.3 Creating carrier sentences

Carrier sentences are created to encode sentence patterns. For example, the carrier

sentence for “*This colonial home is at Pleasantville*” is “*This \$STYLE home is at \$TOWN*”, Where \$STYLE and \$TOWN are variables. Each variable can take one or more values. For example, the values for \$STYLE includes *colonial* and *contemporary*. The main reason for using carrier sentences instead of the instances themselves is that each variable in a carrier sentence can later be instantiated with different values to generate new corpus instances. For example, given the same carrier sentence, we can generate another instance “*This colonial home is at New Castle*”, which may not be in the corpus. In this section, we focus on the production of carrier sentences. Then, in the next section, we describe an algorithm for duplicating and instantiating carrier sentences.

To construct carrier sentences, first, we remove unusable sentences or sentence segments. The unusable sentences/segments contain information that cannot be generated because of lacking appropriate inputs. After removing unusable sentences/segments, we use domain concepts to replace those words realizing the concepts. In addition, we remove repetitive carrier sentences because we systematically duplicate carrier sentences based on the design principles during variable instantiation.

Collecting carrier sentences from a variety of resources is one way to improve semantic and syntactic coverage because most carrier sentences are directly from these resources. However, existing carrier sentences may not cover every domain concept. To convey uncovered domain concepts, we specifically construct new carrier sentences. In addition, whenever possible, we add new paraphrases for each carrier sentence to increase syntactic coverage.

In the following, we illustrate a procedure that systematically instantiate variables in carrier sentences.

## 2.4 Instantiating carrier sentences

As we described before, during carrier sentence creation, we focus on semantic and syntactic coverage. During instantiation, however, our primary concerns are prosodic and word coverage.

The instantiation process is separated into two steps: enumerating possible values for each

variable and duplicating/instantiating carrier sentences. we illustrate them one by one.

**Enumerating values** Before a carrier sentence can be instantiated, we need to know the values of each variable. Ideally, we should cover all the possible values for each variable to ensure word coverage. In practice, the values of some variables are either impossible to enumerate or too large to enumerate. Among them, proper names and numerical variables post the biggest challenges.

In terms of proper names, such as people’s names, the possible values are too large to enumerate. Thus, one typical strategy is to cover the most common proper names and hopefully they will cover most names to be generated.

In terms of numeric variables, such as zip codes, and house prices, usually it is impossible to list all the values. However, for numeric variables, word coverage is not difficult. For example, for zip codes, ten digits will be enough. For house prices, numbers from one to nineteen plus twenty, thirty, to ninety and plus million, thousand, hundred will be sufficient. In addition to word coverage, since the same digit may sound differently in speech, prosodic coverage is also a concern. For example, the 1s in the zip code 10511 may all sound differently due to prosodic variations. Thus, it is a good idea to cover all the 1s in a corpus. A typical solution to this problem is to analyze the prosodic patterns of each variable and cover not only the digits but also each prosodic realization of the digits. In our zip code example, there are two ways of listing possible values: First, to cover the most common zip codes. In SEGUE, we actually cover all the zip codes because our application only applies to houses in a particular county. But for applications where enumerating all zip codes is impossible, a word and prosodic coverage-based design is needed. The goal is to have all the digits appear in each position at least once because they may have different stress patterns. In our zip code example, only ten zip codes are needed for both word and prosodic coverage : 12345, 23456, 34567, 45678, 56789, 67890, 78901, 89012, 90123, 01234. When SEGUE generates a new zip code such as 10025, the first 1 will be from the first 1 in 12345, the second 0 will be from the second 0 in 90123, and the third 0 will be from the third 0 in 89012 etc. Ideally, we should also consider co-articulation. However, it will produce too many

combinations. One way to alleviate the influence of co-articulation is by instructing the speaker, who reads the scripts to put a little silence between numbers.

**Duplicating and instantiating carrier sentences** The main goal in duplication is to generate enough carrier sentences so that we have sufficient number of instances to cover all the possible values of each variable at least once. Moreover, because words in different positions may associate with different prosodic patterns, in order to increase prosodic variations, we also want to make sure that each value also appears in every position at least once. For example, the word *colonial* in *This colonial house is in Pleasantville* may sound differently from the *colonial* in *The style of the house is colonial*. Thus, during instantiation, we want all possible house styles appear in each of the two places at least once. Currently, we categorize all the possible sentence positions into three classes : sentence initial, sentence middle and sentence final. The main reason for this generalization is to scale down the number of instances needed to cover position variations. However, fine-grained classifications may produce better results if the total number of instances is not a concern. In addition, we also want to duplicate as few carrier sentences as possible to control the overall corpus size because manual annotation is often needed for corpus-based CTS generation. Thus, we want each carrier sentence simultaneously serves as many purposes as possible.

One typical way to instantiate carrier sentence is to use a Context Free Grammar (CFG)-based generation approach. But this may generate too many instances. For example, given two carrier sentences : *This \$STYLE house is in \$TOWN* and *This \$TOWN is the home of this \$SYTLE house*, and two values for each variable : *colonial and contemporary* for \$STYLE, *Pleasantville and New Castle* for \$TOWN, the CFG-based approach generates eight instances while only four instances are enough to have both the position and word coverage

Colonial+Pleasantville  
 Colonial+New Castle  
 Contemporary+Pleasantville  
 Contemporary+New Castle  
 Pleasantville+Colonial  
 Pleasantville+Contemporary  
 New Castle+Contemporary  
 New Castle+Colonial

**CFG output**

Colonial+Pleasantville  
 Contemporary+New Castle  
 Pleasantville+Colonial  
 New Castle+Contemporary

**Ideal output**

The algorithm we introduce here accomplishes the same word and position coverage with less carrier sentences than the CFG-based approach. Figure 1 show the pseudo code for duplicating and instantiating the carrier sentences :

**Duplication:**

(1) For each variable  $V_i$  in the domain :

$N_{vi}$  = the number of possible values of  $V_i$

1.1 for all the carrier sentences  $C_j$  in the corpus  
 First( $V_i$ ) = the number of  $C_j$  where  $V_i$  is at the beginning.

1.2 for all the carrier sentences  $C_k$  in the corpus  
 If First( $V_i$ ) >=  $N_{vi}$  Then  $N_{vj}$ =0  
     Else  $N_{vj}$ =Round( $N_{vi}$ /First( $V_i$ ))-1

    If  $V_i$  appears first in  $C_k$  Then Duplicate  $C_k$  for  $N_{vj}$  times  
     Repeat Step 1.1 and 1.2 for  $V_i$  at sentence middle and final positions on the new corpus.  
     Repeat (1) for all the variables in the domain on the new corpus.

**Instantiation:**

(2) For each variable  $V_i$  in the domain

2.1  $LIST_{vi}$  = the list of all the possible values of  $V_i$

2.2 For all the carrier sentences  $C_j$  in the corpus  
     If  $V_i$  is at the beginning of  $C_j$  Then  $Va$ =rotate( $LIST_{vi}$ )  
         Replace  $V_i$  in  $C_j$  with  $Va$

    Repeat step 2.2 for  $V_i$  at sentence middle and final position.  
     Repeat (2) for all the concepts in the corpus

**Figure 1: An Algorithm for Instantiating Carrier Sentence**

In Figure 1,  $V_i$  is the current variable,  $C_j$  and  $C_k$  are the current carrier sentence,  $N_{vi}$  and  $N_d$  are the number of possible values for variable  $V_i$  and the number of duplications needed for a carrier sentence. For each variable at each sentence position, we check whether there is sufficient number of carrier sentences to cover all the values of that variable. If the answer is yes, no duplication is needed. Otherwise, the system computes how many more carrier sentences are needed and duplicate carrier sentences evenly across all the related carrier sentences. In addition, each time new carrier sentences are created, they are put back to the corpus so that the computation for a different variable at a different position will take these new carrier sentences into consideration. This is a way to avoid generating too many carrier sentences. In step (2), the system replaces each variable with its values systematically.

For SEGUE, so far we have collected and created over 300 carrier sentences. After duplication and instantiation, there are about 800 instances in the final corpus. In the following, we describe how each corpus instance is annotated to facilitate instance-based CTS generation.

For simple applications, carrier sentences themselves have been used directly in corpus-based NLG (Ratnaparkhi, 2000). However, they may not be comprehensive enough for more sophisticated applications. For example, unlike domain concepts, relations are not explicitly annotated in a carrier sentence. Thus, given two concepts like \$HOUSE and \$TOWN as input, in principle, without indicating their relations, it is hard if not impossible to decide which sentence to choose: \$HOUSE is located in \$TOWN or \$HOUSE is close to \$TOWN. In addition, carrier sentences do not encode discourse influence, which may affect a CTS system’s ability in generating coherent discourses. Moreover, carrier sentences do not encode the intentions of an utterance. Intentions are critical for conversation systems.

In SEGUE, we employ a comprehensive representation of corpus instances. Each training instance is associated with two annotation trees: a semantic tree (SemTree) that represents the meaning of a sentence and a Realization Tree (ReaTree) that represents the syntactic, lexical, prosodic and acoustic realizations of the meaning. Both trees are represented in XML format. In the following, we describe the features represented in these trees.

### 3.1 Semantic Tree (SemTree)

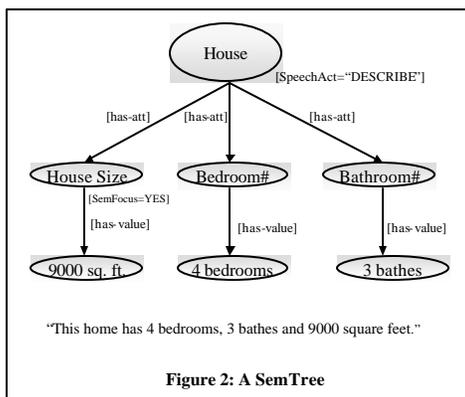

Figure 2 shows a SemTree for the sentence *This home has 4 bedrooms, 3 bathes and 9000 square feet.* It encodes domain concepts, such as BEDROOM# and HOUSESIZE. In addition, it also encodes relations between concepts, such as HAS-ATT and HAS-VAL, both are typical relations in RIA’s ontology. Overall, a SemTree is an aggregation of domain relations and concepts. In addition, it also represents speech acts and semantic focus, which are the intention

of a sentence. Currently, the speech acts covered in SEGUE include *request, describe, confirm, help, greet, goodbye,* and *acknowledge.* Among them, *describe* and *request* are the most common speech acts in information-seeking applications. *Semantic focus* marks the attentional focus a speaker wants to emphasize so that special syntactic constructions, such as pre-position, or prosodic constructions, such as stress, can be used to realize the intention effectively. For example, if a speaker wants to emphasize that a house is huge, she may mark \$HOUSESIZE the semantic focus.

### 3.2 Realization tree (ReaTree)

ReaTree encodes features related to how meanings are realized in speech. Since the same input can be realized in many different ways due to discourse, syntactic, lexical, prosodic and acoustic variations, a ReaTree should cover all the relevant features.

The biggest challenge in encoding all these information in a ReaTree is that overall there are three different tree structures to be represented in a ReaTree: *a syntactic tree* encoding the syntactic constituent structure, *a semantic tree* encoding a SemTree equivalence, and *a prosodic tree* encoding a prosodic constituent structure. Moreover, there is no simple one-to-one mapping between two different trees. For example, there is enough phonological evidence indicating that there is no direct mapping between a syntactic tree and a prosodic tree.

To solve this problem, the ReaTree representation is primarily based on a sentence’s syntactic structure. On top of the syntactic tree, we use a set of features to mark the underlying semantic and prosodic structure. In addition, we also include features that are essential for discourse generation and speech synthesis. Here are the main features annotated in a ReaTree :

**Discourse feature** It encodes whether a syntactic constituent is the *topic* (or *theme*) of a sentence. It is useful in generating context-appropriate sentences. For example, one strategy to maintain discourse coherence is to keep the current sentence *topic* the same as the discourse focus.

**Syntactic features** Main syntactic features annotated in a ReaTree include *syntactic constituent structures, syntactic categories (cat), grammar roles (role), syntactic functions (Syn\_fun)* and *part-of-speech (pos).* Syntactic

features are used mainly for reconstructing new sentences. For example, *Syntactic structures* are encoded as hierarchical syntactic trees. Each subtree or branch in a syntactic tree is a potential building block for new syntactic trees. In addition, *syntactic categories (cat)*, such as whether a phrase is an NP, VP or ADJP, also help us decide whether two or more phrases can be combined to form a new phrase/sentence. *Grammar Roles*, such as whether a constituent is a subject, object or subject complement, provide more constraints on whether a syntactic constituent can be reused in a new sentence. *Syntactic functions* indicate whether a word or phrase is the *head* or *modifier* of a constituent. Finally, *part-of-speech (pos)* is the syntactic category of a word.

**Semantic features** For each syntactic constituent in a ReaTree, we also use the feature *concept* to encode the corresponding concept/relation realized by this constituent. Since the same concept/relation is also defined in the SemTree, *concept* establishes a link between a concept/relation in a SemTree and its realization in a ReaTree. Thus, it essentially defines a mapping between a SemTree and the associated ReaTree.

**Lexical feature** Right now, it only has one feature called *text*, which is the exact wording used to convey a concept or relation.

**Prosodic features** The main prosodic features encoded in a ReaTree are the four main ToBI<sup>1</sup> features: *break index*, *pitch accent*, *phrase accent*, and *boundary tone* (Silverman 1996). *Break index (index)* describes the relative levels of disjuncture between two adjacent orthographic words. Five levels of disjuncture, from 0 to 4, are defined in ToBI, where 4 marks the end of an intonational phrase boundary, the most significant prosodic constituent boundary, and 3 marks an intermediate phrase boundary, the second most significant prosodic phrase boundary. In addition, 1 is the default boundary and 0 means no juncture between two adjacent words. Thus *break index* essentially encodes a hierarchical prosodic constituent structure. In addition to *break index*, *pitch accent (accent)* is associated with a significant excursion in a pitch contour. It often marks the lexical item with which it is associated as prominent. Both phrase

accent (Pa) and boundary tone (Bt) control the shape of a pitch contour towards or at the end of an intonational or intermediate phrase.

**Acoustic features** They are encoded as pointers to a parametric segment database in which temporal sequences of vectors of parameters of speech segments are stored. Typical acoustic features encoded in the database include waveforms and parameters related to pitch, duration and amplitude.

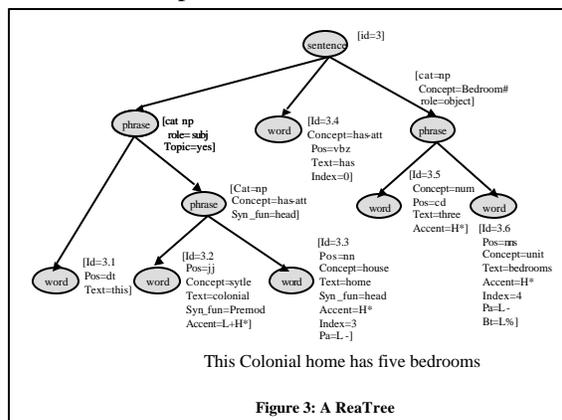

Figure 3 shows an example of the ReaTree of *This colonial home has five bedrooms*. In this representation, there are four basic elements: *sentence*, *clause* (not in the example), *phrase*, and *word*. A *sentence* element is associated with a unique sentence id, pointing to the corresponding SemTree. In addition, *phrase* is associated with features such as *concept*, *syntactic category*, *grammar role*, and *syntactic function*. In addition, it also associates with discourse features such as whether a phrase is the *topic* of a sentence. A *clause* is an embedded sentence. It associates with features similar to those of a phrase. Finally, the main features associated with a word include the text itself, the part-of-speech, the syntactic function, the associated ToBI prosodic features and an unique word id, pointing to the acoustic parameters represented in the speech segment database.

Finally, both the SemTree and ReaTree are represented in XML format because XML is flexible enough to represent complicated structures, and at the same time, it also facilitates parsing and searching that are essential for instance-based learning. Figure 4 shows a simplified ReaTree for *The home is located on 2 acres* in XML format.

<sup>1</sup> ToBI is a prosody annotation convention for American English.

```

<?xml version=1.0 encoding=UTF-8 ?>
<!-- The home is located on 2 acres-->
<sentence id=4>
<ph cat=np role=subj topic=yes>
<word id=4.1 text=the pos=dt/>
<word id=4.2 text=home pos=NN concept=house
syn_fun=head accent=yes break=3 pa=L-/>
</ph>
<ph cat=vp role=pred >

#### 4 Using the corpus for generation

In the following, we briefly discuss how the annotated speech corpus can be used in CTS generation. Instance-based learning is lazy learning. It focuses on how to find similar instances in the training corpus and how to reconstruct new instances if a proper training instance is not found. There are three elements in the core of instance-based learning: similarity metrics, search algorithms, and reconstruction processes. Among them, the definitions of similarity metrics are based on the features annotated in the corpus. In addition, we employed a tree-based searching and matching algorithm that is also based on the structures of the annotated instances. Since the detailed descriptions of the similarity metrics as well as the searching and reconstruction algorithm are covered in another paper, in the following, we briefly describe how speech can be generated based on annotations in a SemTree and ReaTree.

Our generation algorithm starts with a DIFF function that measures the difference (or similarity) between the SemTree of a new input and those of corpus instances. To narrow down the search space, we focus on the top N matching corpus instances. If the result of DIFF for the top-matching training instance equals to zero, indicating an exact match, the entire matching instance is reused. In this case,

SEGUE not only reuses the sentence structure and the wording but also the pronunciation, prosody and waveforms. Apparently, the resulting speech has high quality. In general, for a domain-specific application, if a corpus is designed properly, there will be a significant number of cases falling in this category. However, if the result of DIFF is greater than zero, a set of revision operators are generated based on the difference. Typical revision operators include *remove*, *insert*, and *replace*. The *remove* operator deletes extra concepts or relations as well as their associated subtrees. The *insert* operator adds a new concept or relation. The *replace* operator only applies to *has-val* relations. It instantiates a variable with a different value. For example, if the input Semtree is shown Figure 5, and the closest matching training SemTree is shown in Figure 2, the resulting DIFF operators will be:

1. remove has-att (House, HouseSize)
2. insert has-att(House, HouseType)
3. replace has-value (bedroom#, 4, 3)
4. replace has-value (bathroom#,3,2)

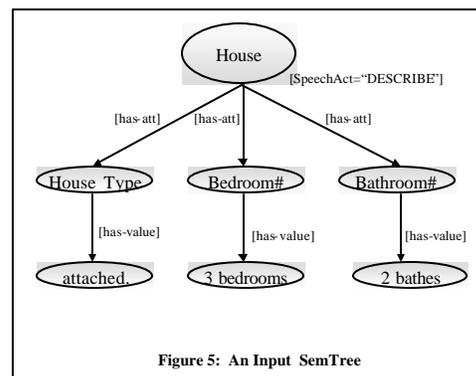

Figure 5: An Input SemTree

Given a set of revision operators, the next step is to transform the corresponding ReaTree into one that can convey the meanings of the input SemTree. In general, each operator is associated with a cost function. The overall cost function is a weighted combination of five subordinate cost functions: the *discourse cost*, *syntactic cost*, *lexical cost*, *prosodic cost* and *acoustic cost*. All the cost functions measure the impact of an operator on a ReaTree. For example, *syntactic cost* measures how a revision operator affects the appropriateness of the syntactic structure of a ReaTree. If an operator has little impact on the soundness of a syntactic structure, the *syntactic cost* will be low. In contrast, if applying an operator results in

incomplete structures, the syntactic cost will be high. Similarly, in term of acoustic cost, if applying an operator, such as *insertion*, results in significant discontinuity between existing and new speech segments, the acoustic cost will be high.

In order to apply a *remove* operator to a ReaTree, the system first searches for a subtree that conveys the specified concepts/relation. Breaking a link on the subtree removes a concept or relation from the ReaTree. Breaking different links on the tree results in different *remove costs*. Similarly, when an *insert* operator is applied, the system first searches for a tree/subtree that communicates the specified relation, then it decides where and how to append the tree/subtree to a ReaTree. The difference in selecting a subtree as well as the difference in choosing a location to append the subtree may result in different *insert costs*. The *replace* operator searches for all the occurrences of a variable and replaces the existing value with a specified value. A *replace* operator is also associated with a *replace cost*. Depending on which occurrence of the word/phrase is used as the replacement, the *prosodic cost* and *acoustic cost* will be different which in turn results in different *replace costs*. After applying all the operators, the lower the overall cost, the better the overall generation quality. After we repeat the entire process to convert the top N matching ReaTrees, the one with the lowest cost is the one to be generated by SEGUE.

## 5 Related Work

Instance-based domain-specific TTS is quite common (Donovan, 1997, Taylor, 2000). In contrast, most NLG systems use grammar-based approaches (Elhadad, 1993, Lavoie, 1997). Recently, machine learning-based NLG gains attentions (Ratnaparkhi, 2000, Walker, 2001, Oberlander, 2000, Varges, 2001, Langkilde, 2000). However, except for a few template-based systems (Yi, 1998), most CTS systems still use different platforms for NLG and speech synthesis. This uncoupled CTS architecture has inherited integration problems. Until now, designing a single corpus for both NLG and speech synthesis in integrated CTS generation has not been systematically addressed.

## 6 Conclusions

In this paper, we present a new uniform framework for systematically generating both text and speech using a single speech corpus. One of our research foci is on the design of a speech corpus for both text and speech generation. This framework facilitates the reuse of sentence structure, wording, prosody and speech waveforms simultaneously. Our initial results demonstrate the effectiveness of this approach.
