Contents

1. Overview

The goal of our project was to develop an interactive, picture-based version of the popular memory game played with cards, so called Pelmanism. The basic idea of Pelmanism is that a player should match two same pictures on the screen, recalling what he or she has seen before. In the beginning of the game, the back side of all the pictures is shown, hiding the front image. Then, the player turns over two cards in every turn. If the two pictures match, these are cleared from the screen; otherwise, the pictures are flipped over again. The game is over when the last pair is matched. The objective is to clear the screen in the lowest number of turns. Figure 1.1 illustrates a game of Pelmanism.

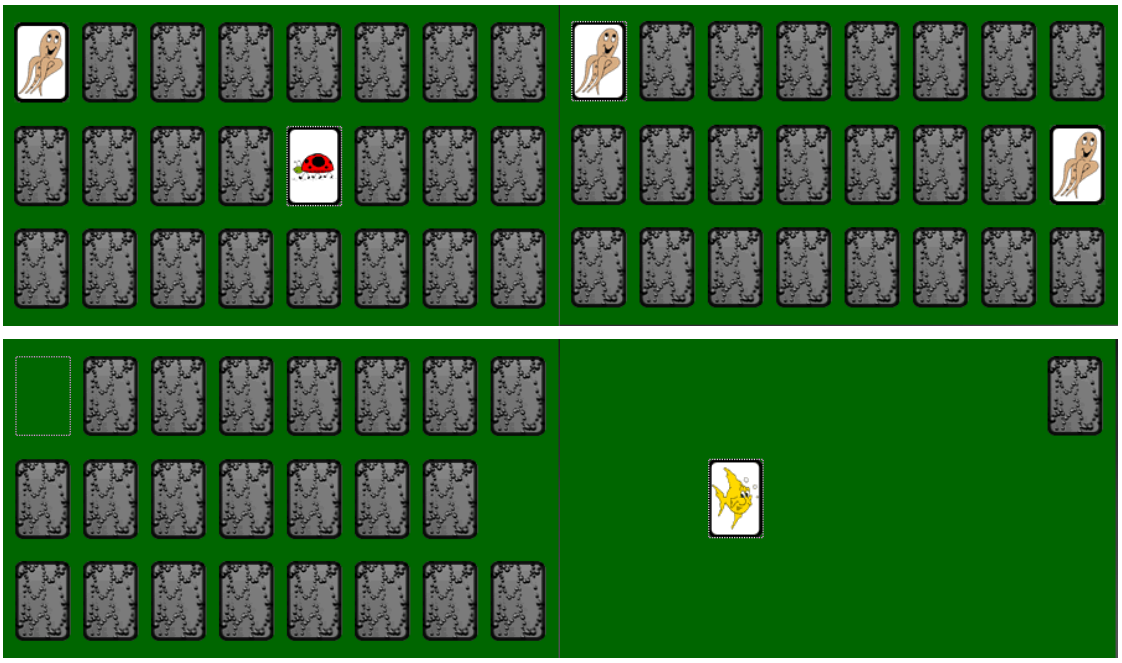

Figure 1.1: An illustration of Pelmanism

In our implementation of the game, we read pictures pre-stored in the SD card in JPEG format. The pictures are then decoded using a JPEG decoder which is implemented in software. The decoded pictures are then transferred to the on-board SRAM. These are then read by the VGA controller and displayed on the screen. One of the features of our game is animation effects during game play which is implemented entirely in hardware.

2. Architecture

In general, the design is divided into the hardware part and the software part. The main structure of the hardware design is shown in Figure 1.2 and the software design is shown in Figure 1.3.

The function of the SD card controller is interface the SD card slot and read pictures from it. The SRAM stores the pictures once it is transferred from the SD card. The VGA controller is the main hardware component. It interacts with the VGA DAC and provides it with proper signals. It reads the data from the SRAM and also contains the animation logic which is triggered by user actions. The PS2 controller's function is to provide interface with the mouse. The SDRAM stores the software program.

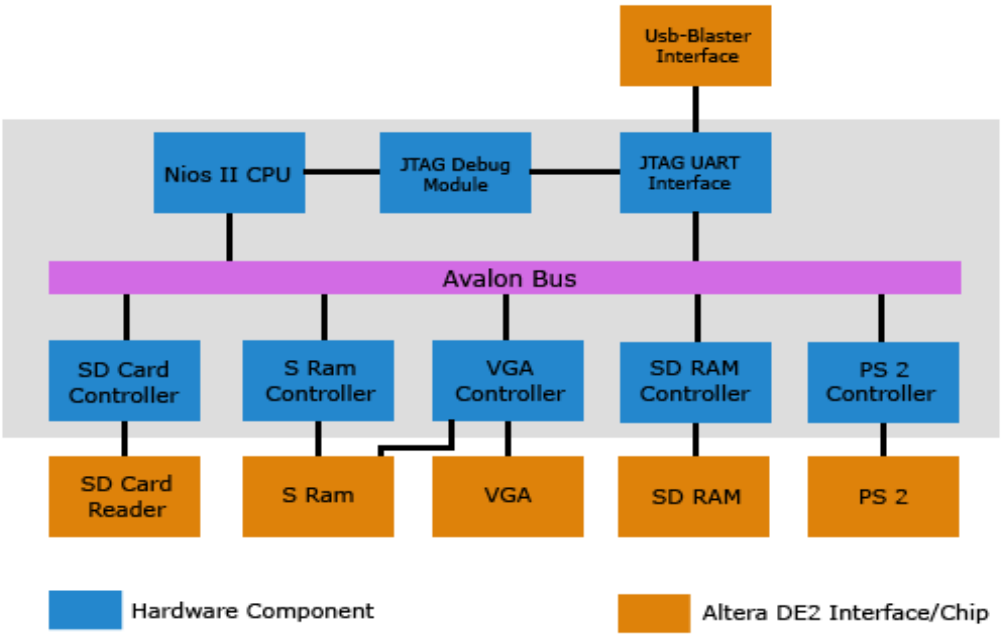

Figure 1.2: Overall structure of our hardware design

The software initializes and controls the peripherals, decodes the pictures with the JPEG decoder and transfers it to the SRAM. It also has the code to read the FAT file-system of the SD card. The mouse is movement is processed by the software and then the actions are communicated to the VGA controller.

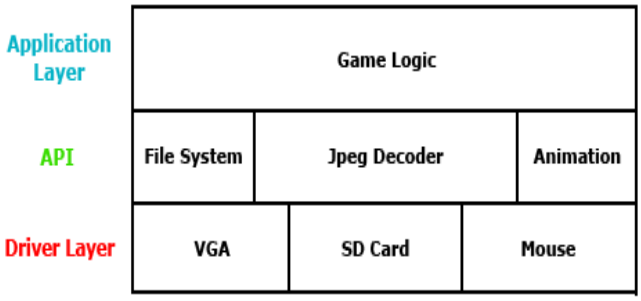

Figure 1.3: Overall architecture of our software design

2. Hardware Design

2.1 VGA Controller

One of the critical **hardware** components that we have implemented was VGA controller which is talking to VGA DAC **and** SRAM presented on DE2 board. Porch values, sync declarations and other important values for 640x480 resolution are already defined in the vhdl file in lab3 and we have used that in our controller. We have added code that helped us to achieve our expectations from VGA controller. We will talk about *cursor drawing*, *SRAM interface*, *pixel drawing* and lastly *animation/visual* effect in this part. The memory mapped I/O can be depicted as below:

Address Value	Processes
0x00	Cursor X & Y pos
0x01	
0x02	SRAM r/w command
0x03	Sprite Status Information (clicked image array)
0x04 - 0x13	Animation - Visual Effect

Fig 2.1 Address Space of VGA-Controller

To make user interface practical, we implemented PS-2 mouse to our system which you can find details about that hardware component in this report. We have defined a two color cursor sprite (the way we defined the ball for lab3) in VGA controller with address 0x00 reserved for it. Note that we use **32bit data bus** for transactions so we can able to send both X and Y positions of the cursor from Nios-2 using only one transaction. The protocol is pretty simple. Nios-2 calculates the new coordinates of a cursor (setting a default starting point 0,0 in the very beginning and calculating the new coordinate using ps-2 controller's output) and puts the x coordinate to the first ten bits and adds y coordinate to the second ten bits of the 32bit array. Therefore 9 down to 0 holds X coordinate and 19 down to 10 keeps Y coordinate value and VGA controller, after receiving this array, splits it properly and draws the cursor depending on the values. Moreover cursor drawing, as usual, has the highest priority (i.e. it is in the highest layer and can overdraw pictures, border etc.).

VGA component, after 16 images are saved into SRAM (check SRAM controller), starts drawing the sprites for 16 predefined rectangle areas. Reading from SRAM and drawing the resulting pixels is actually pretty straightforward. We set "read" flag to "0" from Nios-2, indicating that write phase has been finished, and send that flag to the address 0x02. After that time, any SRAM address value that is being sent by Nios2 will let VGA controller to grab that information from SRAM and show it (with an appropriate animation).

We assume that SDCard holds images that have the same resolution that we have defined for the GUI. You can find the illustration of our GUI below:

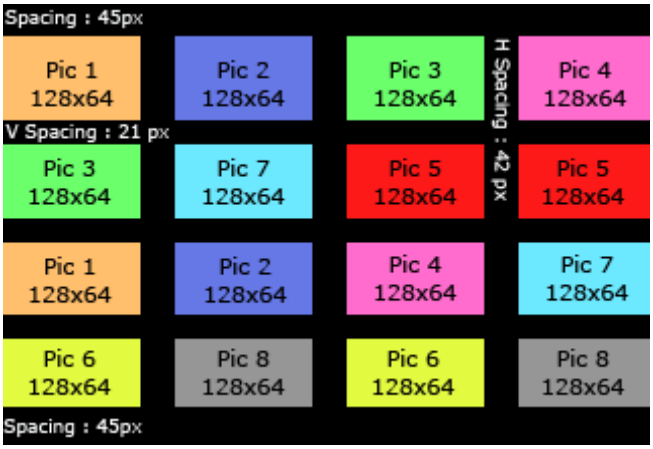

Fig2.2 GUI that depicts the sprites and spacings

We changed the hardcoded resolution to make the animation logic simpler, which is now composed of the two's power (128x64) and any division/multiplication is done by shifting left or right easily. Vertical and Horizontal spacing values are selected such that the aspect ratio is kept 2:1 and there isn't any wasted space horizontally.

Address Value	Processes
0x00	Cursor X & Y pos
0x01	
0x02	SRAM r/w command
0x03	Sprite Status Information (clicked image array)
0x04 - 0x13	Animation - Visual Effect

Fig2.3 Addressing scheme

Whenever the player clicks an image, Nios2 sends a clicked image array to VGA controller's 0x03 address (which is all zeros in default). Clicked image array is a 32bit wide array and the first 16 bits hold information about whether corresponding sprite has been clicked or not. The higher 2 bytes hold whether sprite is still valid (when corresponding bit is zero) or should be removed (when set to one). That is to say, the first sprite will first check the sixteenth bit of the array and if it is set to zero, it assumes that the sprite hasn't been removed yet and will check zero'th bit to check whether it has been clicked or not. If the value is zero, it will show the background image (the last image in the Sram and starting address is hardcoded) otherwise it will show the corresponding image with selected animation (again for each sprite, the Sram address that they should start reading is known apriori). When the user finds two copies of an image, it will be removed from the screen by setting the corresponding bit to '1' by Nios-2 (from the

higher two bytes of clicked image vector). If user clicks two different images, Nios2 will wait some time and folds off both images by showing the background. This is done by setting corresponding clicked image vector to '0' (from the lower two bytes of clicked image vector). One example can be shown as below:

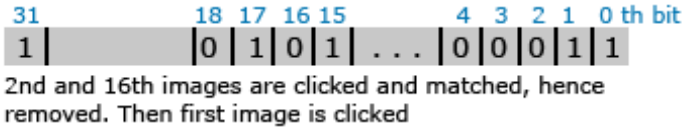

Fig2.4 Sample clicked image array

Note that we are using 5 bits instead of 10 bits for each color channel to save space and make the logic simpler. Therefore 15 bits is enough for a pixel to represent that can be saved and retrieved in one transaction. While sending to VGA DAC we simply copy the higher 5 bits (the actual pixel value that we did get from SRAM) to lower 5 bits and send 10 bits. Each picture will take 128*64*2 (16.384 bytes) bytes of space since each pixel needs 2 bytes. Therefore, total of 128*64*2*17 (16 images and the background) is used from SRAM. It is exactly 272Kbytes and easily fits to 512k SRAM we have.

2.1.1 Animation Effects

Animation Effect:
We have two types of animations in our project implemented entirely in hardware.
1) Expanding and squeezing
2) Fading out.

Expanding and Squeezing:
Whenever the player clicks the back image, it is turned over and it the original picture is revealed.
This animation consists of squeezing the back image and expanding the front image. When the picture needs to be turned to the back side, the reverse process takes place. i.e. expanding the back image and squeezing the front image. When this is done, it gives the impression that the picture is turning over. In order to realize this effect, we implement and offset table of size 30 x 128. The row size is 30 because the animation lasts for30 frames. In each frame, the row corresponding to the animation state is read. For example, in the 15^{th} frame of the animation, the 15^{th} row elements will be read. In the offset table, there are dummy values (255) and real offset values. If the column is 255, then that pixel is displayed as black. Otherwise the offset is added to the current value of the read address of the SRAM. In successive rows, the number of black pixels (255) values is reduced successively, thus the image expands. The reverse process happens for the squeezing effect.

Fading out:
The fading out animation takes place when two pictures are matched and both need to be cleared off the screen. While clearing, instead of just disappearing from the screen, the pictures fade out giving a nice effect. In oorder to implement this animation, we converted RGB value to YUV value. After converting them, we decreased Y value according to the frames, and converted to RGB again. Converting RGB into YUV is through the following matrix transformation.

$$\begin{bmatrix} Y' \\ U \\ V \end{bmatrix} = \begin{bmatrix} 0.299 & 0.587 & 0.114 \\ -0.14713 & -0.28886 & 0.436 \\ 0.615 & -0.51499 & -0.10001 \end{bmatrix} \begin{bmatrix} R \\ G \\ B \end{bmatrix}$$

In pseudo code, this can be expressed as,

// Basic Transform
Y' = 66 * R + 129 * G + 25 * B
U = -38 * R - 74 * G + 112 * B
V = 112 * R - 94 * G - 18 * B

// Scale down to 8 bits with rounding
Y' = (Y' + 128) >> 8
U = (U + 128) >> 8
V = (V + 128) >> 8

// Shift values
Y' += 16
U += 128
V += 128
After we convert the signal into YUV, we decreased luminance according to the frame status.
Y = Y * (1 - current_frame / total_frames)
In VHDL, division calculation is too slow to meet VGA clock timing constraints. Thus, we changed division into shift operation.
Y = Y * (1 – current_frame >> 5)
If it goes to negative, RGB is all set to 0, or we convert the YUV again into RGB value.
C = Y' - 16
D = U - 128
E = V - 128
R = clip ((298 * C + 409 * E + 128) >> 8)
G = clip ((298 * C - 100 * D - 208 * E + 128) >> 8)
B = clip ((298 * C + 516 * D + 128) >> 8)

2.2 SRAM Controller

Even tough SRAM Controller is trivial and already defined in SOPC builder before; we would like to mention how it is going to store our images. The overall picture is as follows: After we fetch the 8 images from SD-Card, the JPEG Decoder will convert them into raster format and the result will be stored into our SRAM randomly (so that the first sprite will not be necessarily the first image and so on). You can find below how SRAM looks like after the first 2 pictures (note that they are randomized by software) are sent to SRAM-controller's 0x00 address and after it saves those to SRAM.

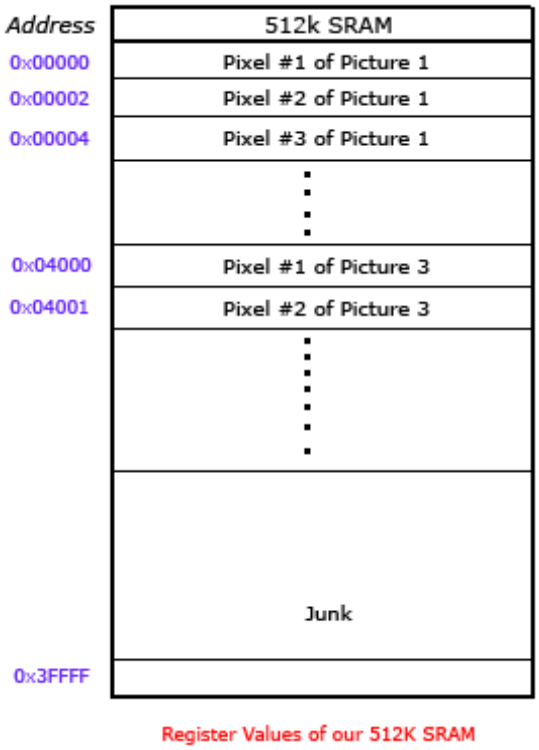

Fig 2.5

2.3 SDRAM Controller

Since we are using SRAM for saving decoded Jpegs (bitmaps), we are not saving our C++ code in the same memory because we find that it would not fit there (after defining Jpeg decoder, file system, drivers and API's in software). That's why we are using off-chip 8Mb SDRAM. The controller definition is trivial since it is already defined in SOPC builder and we don't need to modify it. It is actually using PC100 standard to talk to SDRAM. All of the signals except the Clock signal are already defined in SOPC controller and we have connected our global clock directly to it to make it work. Below you can find the interface between the controller and SDRAM chip itself.

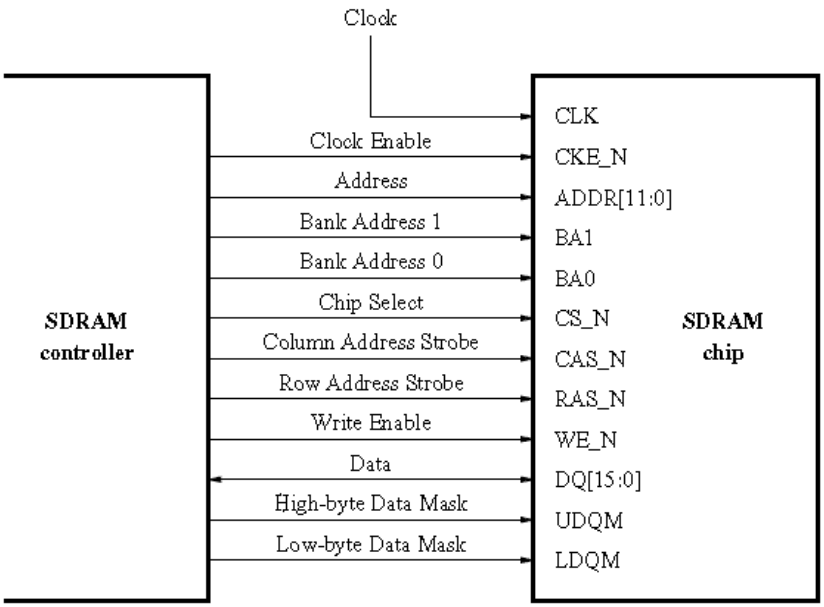

Figure 2. The SDRAM signals.

2.4 PS2 controller

In this project, since PS2 mouse is used, PS2 controller is implemented. Data communication is done according to the clock as follows:

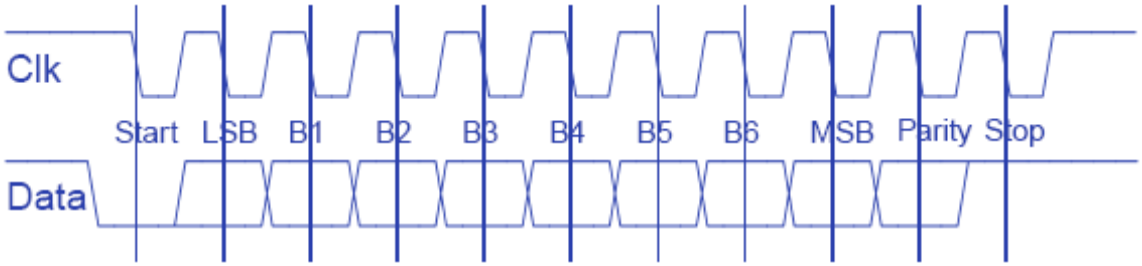

Figure 2.7: The clocks of data communication

Therefore, in the hardware part, PS2 controller reads these data and sends them to the software side. Software mouse driver processes the data: Overflow, Sign, Buttons, X movement and Y movement.

2.5 SD Card Controller

The contents of the SD card are read in the SPI mode. The connection of the FPGA with the SD Card slot is as shown in the diagram below.

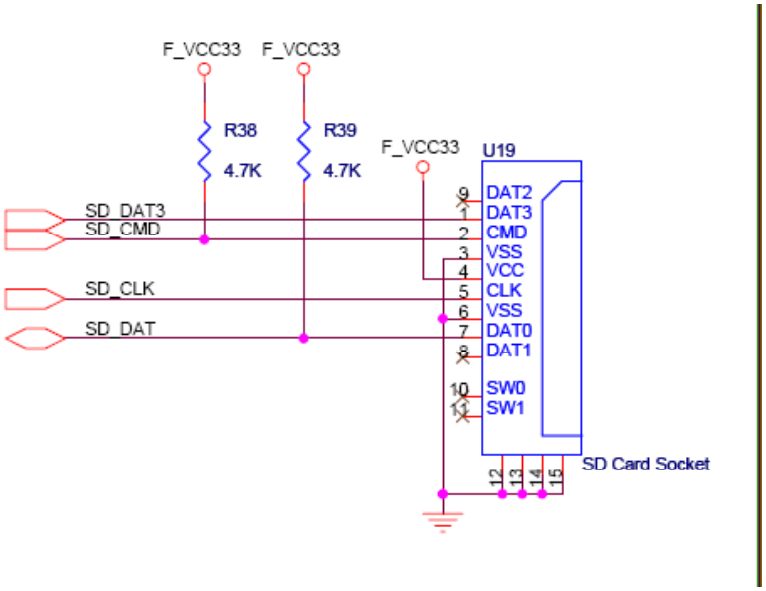

Figure 2.8: Connection with the FPGA

The SD Card supports three protocols which can be divided into two classes, the proprietary SD Mode and the open SPI mode. The DE2 board supports the SPI mode and we will be using this mode. It is to be noted that the SPI communications mode supports only a subset of the full SD communications protocol. However, these functionalities are enough to achieve our purpose. A diagram of the SD card is shown below.

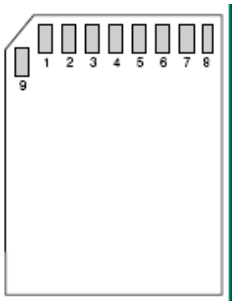

Figure 2.9: SD Card Diagram

The table below lists the pin assignments for the SD card and their functions in the SPI mode.

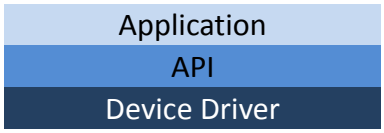
Table 2.1: SD card pin assignments in the SPI mode

Pin	Name	Function (SPI Mode)
1	DAT3/CS	Chip Select/Slave Select (SS)
2	CMD/DI	Master Out Slave In (MOSI)
3	VSS1	Ground
4	VDD	Supply Voltage
5	CLK	Clock (SCK)
6	VSS2	Ground
7	DAT0/DO	Master In Slave Out (MISO)
8	DAT1/IRQ	Unused or IRQ
9	DAT2/NC	Unused

In SPI mode, four signals (clock, data in, data out and chip select) are used for the interface. The clock is used to drive data out on the data out pin and receive data on the data in pin. The software drives commands and data to the SD card over the SD card's data in pin. The software receives response and data from the card on its data out pin. The chip select signal is used to enable the card during data and command transfer. For each of the pins, we have a separate peripheral in hardware. Everything else is controlled by the software.

3. Software Architecture

Our basic software design is 3-layered architecture: application, API, device driver. In the device driver layer, code is written as microcode with C language; in the API and application, it is coded as object-oriented programming with C++ language.



3.1 Device driver layer

Device driver layer abstracts hardware devices such as VGA, SD card and PS2 mouse. In this layer, all the microcode of our game software will be isolated. Basic role of this layer is providing abstracted functionality to the API layer.

3.1.1 VGA driver

VGA driver provides drawing pixels, giving visual effects and cleaning LCD screen or pixel. This driver is interfaced with the hardware VGA interface. Since most of functionalities will be implemented in the hardware side, this driver simply interfaces the hardware

3.1.2 SD card driver

SD card driver communicates with SD card interface in the hardware layer. This driver reads data from SD card or writes data to the card. Additionally, it checks whether SD card is inserted.

3.1.2.1 Protocol

The SD protocol is a simple command-response protocol. All commands are initiated by the master. The SD card responds to the command with a response frame and then, depending on the command, may be followed by a data token indicating the beginning of a bulk data transfer or an error condition. SD commands are issued to the card in a packed command frame, a 6-byte structure sent over the SPI port. The command frame always starts with 01 followed by the 6-bit command number. Next the 4-byte argument is sent, MSB first. The 7-bit CRC with a final stop bit '1' is sent last. All bytes of the command frame are sent over the MOSI pin MSB first. The figure shows the command frame format. The CRC is optional in SPI mode and by default CRC checking is disabled and we would not be enabling it.

Table 3.2: SD Command Format

First Byte			Bytes 2-5	Last Byte	
0	1	Command	Argument (MSB First)	CRC	1

The SD card responds to each command frame with a response. Every command has an expected response type. The type of response used for a particular command depends only on the command number, not on the content of the frame. Three response types are defined for SPI mode: R1, R2, and R3. For example, the R1 response is always 1 byte long and its MSB is always 0. The other bits in the response indicate error conditions.

Table 3.3: R1 Response Format

Bit	7	6	5	4	3	2	1	0
Field	0	Parameter Error	Address Error	Erase Seq Error	Com CRC Error	Illegal Command	Erase Reset	In Idle State

3.1.2.2 Initializing the SD Card in SPI Mode

At power-up, the SD card defaults to the proprietary SD bus protocol. To switch the card to SPI mode, the command 0 (GO_IDLE_STATE) is issued. The SD card detects SPI mode selection by observing that the card select (CS) pin is held low during the GO_IDLE_STATE command. The card responds with response format R1 (as shown above). The idle state bit is set high to signify that the card has entered idle state. The SPI clock rate must not exceed 400 KHz at this stage. Next, at least 74 clocks must be issued by the master before any attempt is made to communicate with the card. This allows the card to initialize any internal state registers before card initialization proceeds. Next, the card is reset by issuing the command CMD0 while holding the CS pin low. This both resets the card and instructs it to enter SPI mode. While the CRC, in general, is ignored in SPI mode, the very first command must be followed by a valid CRC, since the card is not yet in SPI mode. The CRC byte for a CMD0 command with a zero argument is a constant 0x95. For simplicity, this CRC byte is always sent with every command. Next, the card is continuously polled with the commands CMD55 and ACMD41 until the idle bit becomes clear, indicating that the card is fully initialized and ready to respond to general commands.

3.1.2.3 Reading the Images

The SPI mode supports single block read operations only, which will be used to read the images. The READ_SINGLE_BLOCK command with a starting byte address as the argument is to be used. This address must be aligned with the beginning of a block on the media in the valid address range of the card. The SD card then evaluates this byte address and responds back with an R1 command reply. If the read is completed from the SD media without error, a start data token is sent followed by a fixed number of data bytes. The start data token is not sent if the SD card encounters a hardware failure or media read error. Rather, an error token is sent and the data transfer is aborted.

3.1.3 Mouse driver

The PS/2 mouse interface uses a bidirectional serial protocol to transmit movement and button-position data. This driver's input is movement direction, movement speed, mouse click and information whether a mouse is connected to the PS2 port. The standard PS/2 mouse interface supports the following inputs: X (right/left) movement, Y (up/down) movement, left button, middle button, and right button. The mouse reads these inputs at a regular frequency and updates various counters and flags to reflect movement and button states. The mouse has two counters that keep track of movement: the X-movement counter and the Y-movement counter.

The standard PS/2 mouse sends movement/button information to the driver using the following 3-byte packet. The X and Y counters are 9-bit 2's complement values and each has an associated overflow flag. The movement counters represent the amount of movement that has occurred since the last movement data packet was sent to the host (i.e., they do not represent absolute positions.) The movement counters are updated when the mouse reads its input and finds movement has occurred.

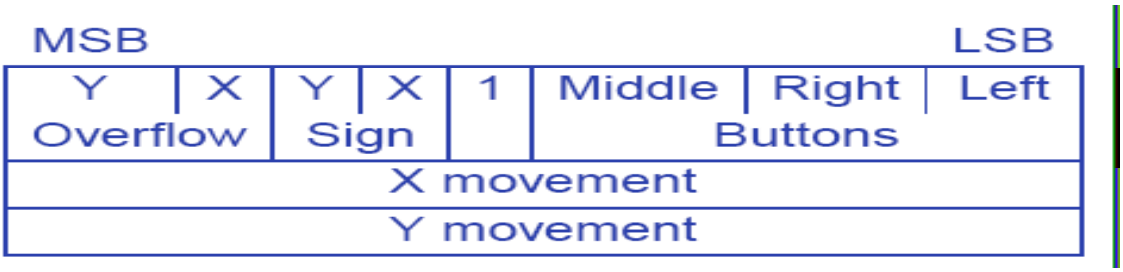


Figure 3.1: The transferring data of PS2 mouse control

Their value is the amount of movement that has occurred since the last movement data packet was sent to the host (i.e., after a packet is sent to the host, the movement counters are reset.) The range of values that can be expressed by the movement counters is -255 to +255. If this range is exceeded, the appropriate overflow bit is set.

The default mode of the mouse is the Stream Mode. However, we are using the Remote Mode of operation. Initially we tried using the mouse in the stream mode but faced some problems. So after the mouse finishes executing the reset sequence, the "Set Remote Mode (0xF0) is sent to the mouse. In this mode the mouse reads its inputs and updates its counters/flags at the current sample rate, but it does not automatically issue data packets when movement has occurred. Instead, the driver polls the mouse using the "Read Data" command. Upon receiving this command the mouse will send a single movement data packet and reset its movement counters. This gives greater control to the software to read the cursor position.

3.2 API layer

API layer gives useful toolsets or specific functionalities to the application layer. Through the API, the application layer can deals with file data, receives mouse status, decodes JPEG image and write text image on the LCD screen.

3.2.1 FAT File-system

The code to read the file system is an altered and simplified version of the FAT module that is part of FreeDos32. The first 512 bytes of the SD card make up the BIOS Parameter Block, which contains the volume information, type of FAT (FAT16 is most common for removable media), location of root directory, location of the FAT table, as well as other information. Files on the disk are broken up into chunks of Clusters (2048 bytes), which contain 8 Sectors (512 bytes) each. The File Allocation Table contains the linked list of all Clusters that make up a complete file. Since we are only interested in reading JPG files on the file system, we only implement the read functionality, and ignore Long File Names (we only read the Short File names in MSDOS 8.3 format). The root directory is read from the file system, and the JPEG files are retrieved. The functions that are used for our purpose are

3.2.2 JPEG decoder

JPEG decoder takes as its input JPEG file and outputs in raster format. Even though it would have been more efficient to be implemented in the hardware side, this decoder is placed in the software side due to the decoding algorithm's complexity. Below is a diagram describing the decoding process.

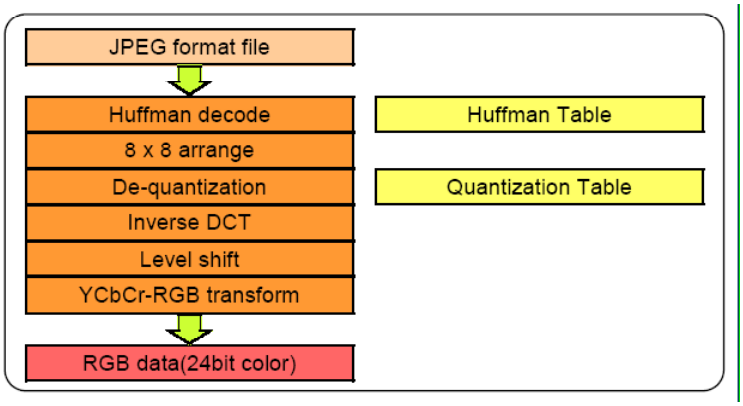

Fig3.2 Jpeg decoding Process

3.3 Application layer

Application layer has game logic. The game logic is simple source codes with deciding whether cards are matched. If they are matched, the cards are disappeared; otherwise, they are flipped back again. Finally, when all the cards are matched, we can restart the game by clicking mouse button again.

4. Who Did What

Can Ilhan:
I worked on VGA-controller component and SRAM controller in the beginning. After I implemented the basics for milestone 1, I have waited the other modules to be complete (sd-card,ps-2, interface). The animation and SRAM interface was non-trivial so after milestone 2, I have worked with my teammates to finalize VGA-controller part. I also worked on debugging software design to check vga-controller is doing its job properly or not.

Chintan Shah:
My main job was to transfer the pictures from the SD card to the SRAM. For this I took help of the sd card controller, the jpeg decoder and the file system implementation of last years imagic project. The porting of the code turned out to be more difficult than expected because we faced some issues in this. First of all, since our application was written in C++, there was some trouble in determining that in order . to combine both C and C++ code we had to define C functions as extern. Initially, we thought that it was a problem related to nios-ide. Also, the imagic code had a bug that instead of reading the boot sector and then using the pointer there to go to the partition, it was directly going to the partition table. Because of this, for each card the offset had to be manually modified. I fixed this part so that it could read from our card. Also the code was put in arranged in a much more intuitive by making classes and putting the functions in the library. After getting the pictures from the sd card, before putting in the SRAM, I implemented a randomizer function so that the cards are arranged in random locations in the screen each time. Once this was completed, I worked with my teammates in debugging problems that arised in the vga controller part and other issues in the software.

Sungjun Kim:
I worked on ps2 mount and SDRAM mount on SOPC in milestone 1. Afterwards, I finished mouse driver and designed software interface in milestone 2. Then, from milestone 3, I switched and focused my work to the hardware side to develop VGA controller. I developed image drawing logic and animation logics in milestone 3. Specifically, my work in milestone 3 was defining and implementing hardware algorithms of reading image data from SRAM, of plotting pixels on the screen, and of giving animation effects (squizing/expanding/fading-out images.) Finally, until final report, I developed game logic with my teammates and fixed VGA controller's bugs.

Zenan Li:
Initially I did the SOPC system generation and configuration in the milestone1. After that, I worked with

my teammates to complete the SDRAM interfacing in milestone2. In the milestone3, when we were working on the animation issues, we were not getting a smooth transition because of problems in the offset table in the expanding and squeezing animation. After careful design of the offset table, I optimized it so that the animation works pretty well and looks highly natural. And in the final part, I implemented some parts of the game logic with my teammates in the software side and tested the whole system to ensure that it works perfectly.

5. Learnings and advice for future students

Over the course of the project, we learnt many things and had some experiences that we would like to share with future students. It is best if the group can have a clear vision of all the aspects of the project from the beginning, because in that case the project design can be easily drawn and separated into independent modules. These can then be divided among the team members. In this way the project can progress efficiently. Initially, we did not have such a clear view as to how we will implement the project. Also, each of the team members had his own opinion of how it could be done. We made the mistake that we did not write down the outputs of our meetings. Because of this, each time we sat down to discuss we had to start from the beginning. So we suggest that during the initial stages, after each meeting the team should write down the summary of the points discussed so that they could proceed from there the next time. Because of our initial mistakes, we could not distribute the work efficiently and this resulted in some delays. This resulted in some situation to case similar to extreme programming where one would write the code and the others would sit around and debug the code. While sometimes useful, overall we think the traditional approach of dividing the project into modules is more efficient. One of our team members is of the view that teams should appoint a team leader who can coordinate the activities of other members. Another important decision is to decide what part of the project should be completed in which milestone. The distribution should be even so that the team is not stretched in anyone of the milestones and it is even better if most of the work can be done in the earlier milestones. Also a key decision in an embedded system project is to decide which components and functionality will be implemented in hardware and which will be implemented in software. This should generally depend on the type of project that one is doing. Hardware is faster than software but at the same time more difficult to implement and debug. For example, in our project we could have implemented the SD card control and the JPEG decoder in hardware instead of software. This would have resulted in much improved performance but with a corresponding increase in complexity. As our application was not so sensitive to timing and speed issues we implemented those in software. But at the same time animation was implemented in hardware considering the above.
