1 Linear Regression

Linear regression helps solve the problem of predicting a real-valued variable y, called the *response*, from a vector of inputs x, called the *covariates*.

The goal is to predict y from x with a linear function. Here is a picture.

[one covariate and a response, and the best fit line]

Here are some examples.

- Given the stock price today, what will it be tomorrow?
- Given today's precipitation, what will it be in a week?
- Given my mother's height, what is my shoe size?
- Others? Where have you seen linear regression?

In the literature, we assume there are p covariates and we fit a linear function to predict the response,

$$f(x) = \beta_0 + \sum_{i=1}^{p} \beta_i x_i.$$
 (1)

The vector β contains the *p coefficients*; β_0 is the *intercept*.

This set-up is less limiting than you might imagine. The covariates can be flexible. Examples:

- Any feature of the data
- Transformations of the original features, $x_2 = \log x_1$ or $x_2 = \sqrt{x_1}$.
- A basis expansion, e.g., $x_2 = x_1^2$ and $x_3 = x_1^3$. Here linear regression fits a polynomial, rather than a line.
- Indicator functions of qualitative covariates, e.g., 1[The subject has brown hair].
- *Interactions* between covariates, e.g., $x_3 = x_1x_2$.

Its simplicity and flexibility makes linear regression one of the most important and widely used statistical prediction methods. There are courses and sequences of courses devoted to linear regression.

1.1 Fitting a regression

Given data $\{(x_n, y_n)\}_{n=1}^N$, find the coefficients β that best predict y_{new} from x_{new} . For simplicity, assume that x_n is a scalar and the intercept β_0 is zero. (In general we can assume $\beta_0 = 0$ by centering the response variables before analyzing them.) There is only one coefficient β .

A reasonable approach is to consider the squared Euclidean distance between each *fitted response* $f(x_n) = \beta x_n$ and the true response y_n , $(y_n - \beta x_n)^2$. Choose β that minimizes the sum of the distances over the data,

$$\hat{\beta} = \arg\min \frac{1}{2} \sum_{n=1}^{N} (y_n - \beta x_n)^2$$
 (2)

This has a closed-form solution both in our simplified case and the more general setting with p covariates. We will get back to this later.

Given a fitted coefficient, we predict the new response by plugging it into the regression equation,

$$\hat{\mathbf{y}}_{\text{new}} = \hat{\boldsymbol{\beta}} x_{\text{new}}.$$
 (3)

1.2 Linear regression as a probabilistic model

Linear regression can be interpreted as a probabilistic model,

$$y_n \mid x_n \sim \mathcal{N}(\beta^\top x_n, \sigma^2).$$
 (4)

For each response this is like putting a Gaussian "bump" around a mean, which is a linear function of the covariates. This is a *conditional model*; the inputs are not modeled with a distribution.

[Draw the graphical model, training and testing]

Linear regression is parameterized by its coefficients. We observe a training set of covariate/response pairs $\mathcal{D} = \{(x_n, y_n)\}$. We want to find the parameter β that maximizes the conditional log likelihood, $\sum \log p(y_n \mid x_n, \beta)$.

Finding this MLE is equivalent to minimizing the residual sum of squares, described above. The conditional log likelihood is

$$\mathcal{L}(\beta; x_{1:N}, y_{1:N}) = \sum_{n=1}^{N} -\frac{1}{2} \log 2\pi \sigma^2 - \frac{1}{2} (y_n - \beta^{\top} x_n)^2 / \sigma^2.$$
 (5)

Optimizing with respect to β reveals

$$\hat{\beta} = \arg\max -\frac{1}{2} \sum_{n=1}^{N} (y_n - \beta^{\top} x_n)^2 / \sigma^2.$$
 (6)

This is equivalent to minimizing the residual sum of squares.

Return to the single covariate case. The derivative is

$$\frac{d\mathcal{L}}{d\beta} = \sum_{n=1}^{N} (y_n - \beta x_n) x_n. \tag{7}$$

(This is multiplied by σ^2 , which is a constant factor.) In this case the optimal can be found analytically,

$$\hat{\beta} = \frac{\sum_{n=1}^{N} y_n x_n}{\sum_{n=1}^{N} x_n^2}.$$
 (8)

This is the empirical covariance between the covariate and response divided by the empirical variance of the covariate.

Foreshadow: Modern regression problems are high dimensional, which means that the number of covariates *p* is large. In practice statisticians *regularize* their models, veering away from the MLE solution to one where the coefficients have smaller magnitude.

Still in the probabilistic framework, let's turn to prediction. The conditional expectation $\mathbb{E}[y_{\text{new}} | x_{\text{new}}]$. This is simply the mean of the corresponding Gaussian,

$$\mathbb{E}\left[y_{\text{new}} \mid x_{\text{new}}\right] = \hat{\beta}^{\top} x_{\text{new}}.$$
 (9)

The variance σ^2 does not play a role in prediction.

With this perspective on prediction, we can rewrite the derivative of the conditional log likelihood,

$$\frac{d\mathcal{L}}{d\beta} = \sum_{n=1}^{N} (y_n - \mathbb{E}\left[y \mid x_n, \beta\right]) x_n. \tag{10}$$

This form will come up again later.

In the more general case, there are p covariates. The derivative is

$$\frac{d\mathcal{L}}{d\beta_i} = \sum_{n=1}^{N} (y_n - \mathbb{E}\left[Y \mid x_n, \beta\right]) x_{ni}.$$
 (11)

This is intuitive. When we are fitting the data well, the derivative is close to zero. If both the error (also called the *signed residual*) and covariate are large then we will move the corresponding coefficient.

2 Logistic regression

We have seen that linear regression corresponds to this graphical model.

[Draw the graphical model, training and testing]

We can use the same machinery to do classification. Consider binary classification, where each data point is in one of two classes $y_n \in \{0, 1\}$. If we used linear regression to model this data, then

$$y_n \mid x_n \sim \mathcal{N}(\beta^{\top} x_n, \sigma^2). \tag{12}$$

This is not appropriate for binary classification.

Q: Why not? The reason is that y_n needs to be zero or one, i.e., a Bernoulli random variable. (In some set-ups, it makes more sense for the classes to be $\{-1, 1\}$. Not here.)

We model p(y = 1 | x) as a Bernoulli whose parameter is a function of x,

$$p(y = 1 \mid x) = \mu(x)^{y} (1 - \mu(x))^{1 - y}.$$
 (13)

What form should $\mu(x)$ take?

Let's go back to our line of thinking around linear regression. We can think of linear regression as a Gaussian whose mean is a function of x, specifically, $\mu(x) = \beta^{\top} x_n$. Is this appropriate here? No, because we need $\mu(x) \in (0,1)$.

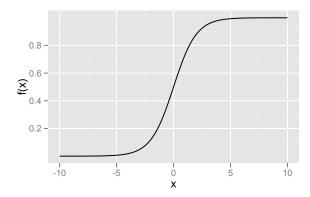

Rather, we use the *logistic function*,

$$\mu(x) = \frac{1}{1 + e^{-\eta(x)}}. (14)$$

This function maps the reals to a value in (0, 1).

- Q: What happens when $\eta(x) = -\infty$?
- Q: What happens when $\eta(x) = +\infty$?
- Q: What happens when $\eta(x) = 0$?

Here is a plot of the logistic function

In logistic regression, as in linear regression, we set

$$\eta(x) = \beta^{\top} x. \tag{15}$$

This specifies the model,

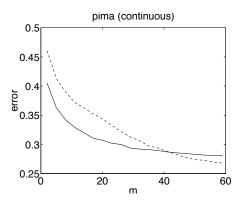

$$y_n \sim \text{Bernoulli}(\mu(\beta^{\top} x_n))$$
 (16)

Note that the graphical model is identical to linear regression.

Important: The covariates enter the probability of the response through a linear combination with the coefficients. That linear combination is then passed through a function to make a quantity that is appropriate as a parameter to the distribution of the response.

Optional: Generative vs. discriminative modeling. As for linear regression we always assume that x_n is observed. Contrasting this with naive Bayes classification, this is a discriminative model. The folk wisdom, made more formal by Ng and Jordan (2002), is that discriminative models give better performance as more data are observed. Of course "more" must take into account dimension and number of data points. (For example, 100 1-dimensional points is "more" than 100 1000-dimensional points.)

Here is an example picture from their paper:

The paper includes many such pictures, for many data sets.

Linear separators and the margin. Suppose there are two covariates and two classes.

[Draw a plane with "+" and "-" labeled points, separable.]

Q: What kind of classification boundary does logistic regression create?

- Q: When does p(+|x) = 1/2? A: When $\eta(x) = 0$
- Q: Where does $\beta^{\top} x_n = 0$? A: A line in covariate space.
- Q: What happens when $\beta^{\top}x < 0$? A: p(+|x|) < 1/2
- Q: What happens when $\beta^{\top}x > 0$? A: p(+|x|) < 1/2

So, the boundary around 1/2 occurs where $\beta^{\top}x = 0$. Thus, logistic regression finds a *linear separator*. (Many of you have seen SVMs. They also find a linear separator, but non-probabilistic.)

Furthermore, those of you who know about SVMs know about the *margin*. Intuitively, SVMs don't care about points that are easy to classify; rather, they try to separate the points that are difficult.

Loosely, the same idea applies here (Hastie et al., 2009).

- The argument to the logistic, $\beta^{\top} x_n$ is the scaled distance to the separator. It is scaled by $||\beta||$.
- What happens to the likelihood of a data point as we get further away from the separator? See the plot of the logistic function. What is the difference between two points one inch apart near the separator and two points one inch apart far from the separator?

- This means that the probability of the data changes most near the line.
- Thus, when we maximize likelihood, what will we focus on? The margin!

2.1 Fitting logistic regression with maximum likelihood

Our data are $\{(x_n, y_n)\}$ pairs (e.g., email features and spam/not spam). Just as we did for linear regression, we fit logistic regression by maximizing the *conditional likelihood*,

$$\hat{\beta} = \arg\max_{\beta} \sum_{n=1}^{N} \log p(y_n \mid x_n, \beta). \tag{17}$$

The objective is

$$\mathcal{L} = \sum_{n=1}^{N} y_n \log \mu(\beta^{\top} x_n) + (1 - y_n) \log(1 - \mu(\beta^{\top} x_n)).$$
 (18)

Define $\mu_n \triangleq \mu(\beta^\top x_n)$, and do not lose sight that it depends on β . Define \mathcal{L}_n to be the *n*th term in the conditional likelihood, $\mathcal{L} = \sum_{n=1}^{N} \mathcal{L}_n$. We find the derivative of the full conditional likelihood with the chain rule on each term,

$$\frac{d\mathcal{L}_n}{d\beta_i} = \sum_{n=1}^N \frac{d\mathcal{L}_n}{d\mu_n} \frac{d\mu_n}{d\beta_i}.$$
 (19)

The first term is

$$\frac{d\mathcal{L}_{\backslash}}{d\mu_n} = \frac{y_n}{\mu_n} - \frac{(1 - y_n)}{1 - \mu_n} \tag{20}$$

We use the chain rule again to compute the second term. The derivative of the logistic with respect to its argument η is

$$\frac{d\mu(\eta)}{d\eta} = \mu(\eta)(1 - \mu(\eta)). \tag{21}$$

(This is an exercise.) Now apply the chain rule

$$\frac{d\mu_n}{d\beta_i} = \frac{d\mu_n}{d\beta^\top x_n} \frac{d\beta^\top x_n}{d\beta_i}$$
 (22)

$$= \mu_n (1 - \mu_n) x_{ni} \tag{23}$$

With this reasoning, the derivative of each term is

$$\frac{d\mathcal{L}_{\backslash}}{d\beta_{i}} = \left(\frac{y_{n}}{\mu_{n}} - \frac{1 - y_{n}}{1 - \mu_{n}}\right) \mu_{n} (1 - \mu_{n}) x_{ni} \tag{24}$$

$$= ((y_n(1-\mu_n) - (1-y_n)\mu_n)x_{ni}$$
 (25)

$$= (y_n - y_n \mu_n - \mu_n + y_n \mu_n) x_{ni}$$
 (26)

$$= (y_n - \mu_n)x_{ni} \tag{27}$$

So, the full derivative is

$$\frac{d\mathcal{L}}{d\beta_i} = \sum_{n=1}^{N} (y_n - \mu(\beta^{\top} x_n)) x_{ni}$$
 (28)

Logistic regression algorithms fit the objective with gradient methods, such as Newton's method. Nice closed-form solutions, like the normal equations in linear regression, are not available. But the likelihood is convex; there is a unique solution.

Note that $\mathbb{E}[y_n | x_n] = p(y_n | x_n) = \mu(\beta^{\top} x_n)$. Recall the *linear regression* derivative. (Warning: In the equation below y_n is real valued.)

$$\frac{d\mathcal{L}}{d\beta_i} = \sum_{n=1}^{N} (y_n - \beta^{\top} x_n) x_{ni}$$
 (29)

Further recall that in linear regression, $\mathbb{E}[y_n \mid x_n] = \beta^{\top} x_n$.

Both the linear regression and logistic regression derivatives have the form

$$\sum_{n=1}^{N} (y_n - \mathbb{E}\left[y \mid x_n, \beta\right]) x_{ni}$$
(30)

(Something is happening here... more later.)

3 Generalized linear models

Linear regression and logistic regression are both *linear models*. The coefficient β enters the distribution of y_n through a linear combination of x_n . The difference is in the type of the response. In linear regression the response is real valued; in logistic regression the response is binary.

Linear and logistic regression are instances for a more general class of models, generalized linear models (GLMs) (McCullagh and Nelder, 1989). In addition

to real and binary responses, GLMs can handle categorical, positive real, positive integer, and ordinal responses.

The idea behind logistic and linear regression: The conditional expectation of y_n depends on x_n through a function of a linear relationship,

$$\mathbb{E}\left[y_n \mid x_n, \beta\right] = f(\beta^\top x_n) = \mu_n$$

In linear regression, f is the identity; in logistic regression, f is the logistic. Finally, GLMs endow y_n with a distribution that depends on μ_n . In linear regression, the distribution is a Gaussian; in logistic regression, it is a Bernoulli.

The generic GLM has the following form,

$$p(y_n | x_n) = \log h(y_n) \exp\{\eta_n^{\top} y_n - a(\eta_n)\}$$
 (31)

$$\eta_n = \psi(\mu_n) \tag{32}$$

$$\eta_n = \psi(\mu_n) \tag{32}$$

$$\mu_n = f(\beta^\top x_n) \tag{33}$$

Note:

- The input x_n enters the model through $\beta^{\top} x_n$.
- The conditional mean μ_n is a function $f(\beta^{\top}x_n)$ called the *response* function or link function.
- Response y_n has conditional mean μ_n .
- Its natural parameter is denoted $\eta_n = \psi(\mu_n)$.

GLMs let us build probabilistic predictors of many kinds of responses.

There are two choices to make in a GLM: the distribution of the response y and the function that gives us its mean $f(\beta^{\top}x)$. The distribution is usually determined by the form of y (e.g., Gaussian for real, Poisson for integer, Bernoulli for binary). The response function is somewhat constrained—it must give a mean in the right space for the distribution of y—but also offers some freedom. For example, we can use a logistic function or a probit function when modeling binary data because both map the reals to (0, 1).

There is a special response function called the *canonical response function*. It is $f = \psi^{-1}$, which maps a natural parameter to the conditional mean that gives that natural parameter. When we use the canonical response function, the natural parameter is $\beta^{\top} x_n$,

$$p(y_n | x_n) = h(y_n) \exp\{(\beta^{\top} x_n)^{\top} t(y_n) - a(\eta_n)\}.$$
(34)

The logistic function (for binary response) and identity function (for real response) are examples of canonical response functions.

3.1 Fitting a GLM

We fit GLM methods with gradient optimization. It suffices to investigate the likelihood and its derivative.

The data are input/response pairs $\{(x_n, y_n)\}$. The conditional likelihood is

$$\mathcal{L}(\beta; \mathcal{D}) = \sum_{n=1}^{N} h(y_n) + \eta_n^{\mathsf{T}} t(y_n) - a(\eta_n), \tag{35}$$

and recall that η_n is a function of β and x_n (via f and ψ).

Define each term to be \mathcal{L}_n . The gradient is

$$\nabla_{\beta} \mathcal{L} = \sum_{n=1}^{N} \nabla_{\eta_n} \mathcal{L}_n \nabla_{\beta} \eta_n \tag{36}$$

$$= \sum_{n=1}^{N} (t(y_n) - \nabla_{\eta_n} a(\eta_n)) \nabla_{\beta} \eta_n$$
 (37)

$$= \sum_{n=1}^{N} (t(y_n) - \mathbb{E}[Y \mid x_n, \beta])(\nabla_{\mu_n} \eta_n)(\nabla_{\beta^{\top} x_n} \mu_n) x_n$$
 (38)

In a canonical GLM, $\eta_n = \beta^{\top} x_n$ and $\nabla_{\beta} \eta_n = x_n$. Therefore,

$$\nabla_{\beta} \mathcal{L} = \sum_{n=1}^{N} (t(y_n) - \mathbb{E}[Y \mid x_n, \beta]) x_n$$
 (39)

Recall that the logistic and linear regression derivatives had this form. These are examples of generalized linear models with canonical links.

On small data sets, fitting generalized linear models is easy in R. Simply use the glm command.
