ABSTRACT

Judicious control of indoor wireless coverage is crucial in built environments. It enhances signal reception, reduces harmful interference, and raises the barrier for malicious attackers. Existing methods are either costly, vulnerable to attacks, or hard to configure. We present a low-cost, secure, and easy-to-configure approach that uses an easily-accessible, 3D-fabricated reflector to customize wireless coverage. With input on coarse-grained environment setting and preferred coverage (e.g., areas with signals to be strengthened or weakened), the system computes an optimized reflector shape tailored to the given environment. The user simply 3D prints the reflector and places it around a Wi-Fi access point to realize the target coverage. We conduct experiments to examine the efficacy and limits of optimized reflectors in different indoor settings. Results show that optimized reflectors coexist with a variety of Wi-Fi APs and correctly weaken or enhance signals in target areas by up to 10 or 6 dB, resulting to throughput changes by up to -63.3% or 55.1%.

1 INTRODUCTION

Customizing the coverage of wireless networks explicitly for built environments is critical. By regulating the physical coverage of each wireless access point (AP), we can enhance signal reception in desired regions while weakening signals in others. It improves the efficiency of wireless infrastructure in buildings by mitigating the impact of building’s insulations, partitions, and interior layouts, reducing harmful interference, and enhancing system security. Such physical confinement of wireless signals serves as a complimentary method to existing network security measures, such as encryption, and hence raises the barrier for attackers.

Achieving this goal is particularly challenging indoors, because of the complex interactions of radio signals with the environment. Existing approaches rely on directional antennas to concentrate signals in desired directions. These approaches, however, have three shortcomings. First, they face a tradeoff between cost and control flexibility. Low-cost directional antennas [8] concentrate signals in a static direction, offering very few coverage shapes. Antenna arrays with more sophisticated control (e.g., arbitrary beam patterns, dynamic configuration) are costly, e.g., $5000+ for Phocus array [6], $200 for an 802.11ac AP [1]. It is because forming a narrow beam needs a large number of antennas, each with a separate RF chain [44]. These additional RF chains lead to a prohibitive cost. Second, they often fail to provide strong security guarantees. On the one hand, fixed-beam directional antennas cannot physically limit signals within an arbitrary area of interest due to their fixed radiation patterns. On the other hand, multi-user beamforming systems (e.g., 802.11ac APs) cannot differentiate intended and malicious clients and strengthen signals for both types of clients. Third, they require significant configuring efforts due to rich multi-path effects indoors [8, 14, 34]. Users must try different antenna configurations to identify the one best matching the desired coverage.

In this paper, we present a low-cost, physically-secure, and easy-to-configure approach that customizes each AP’s coverage without requiring directional antennas. Given the increasing popularity and easy accessibility of 3D printers\textsuperscript{1}, we study the use of 3D-fabricated reflectors produced by 3D digital manufacturing (“3D printing”) to control signal propagation in the space. Specifically, we place a signal reflector around an AP, where the reflector shape is computationally optimized, taking into account the environment (e.g., interior layouts, partitions, AP locations) and the desired signal distribution (i.e., target areas to strengthen or weaken signal strength). The reflector reflects wireless signals to realize a desired coverage. Indeed, anecdotal experiments [2] have demonstrated substantial (29.1%–57.2%) bandwidth gain by placing a soda can behind a Wi-Fi AP to strengthen signal in one direction. Our work generalizes this idea by presenting a systematic approach to optimizing reflector shapes for enabling a rich set of signal distributions.

Our approach provides four benefits. First, it provides strong physical security by limiting the physical reach of wireless signals, hence creating a virtual wall for wireless signals. Second, it relies on a low-cost ($35), reproducible 3D reflector, which can be easily replaced upon substantial changes in the environment or coverage requirement. Third, it offers an easily-accessible and easy-to-configure solution to non-expert users. Users only need to specify coverage requirements and a coarse environment model\textsuperscript{2}, with which our system computes a reflector shape tailored to the built environment. Finally, it is applicable to commodity low-end Wi-Fi

---

\textsuperscript{1}Many online printing services [4, 7] are available when 3D printers are absent.

\textsuperscript{2}Indoor models can be obtained using full-fledged systems (e.g., Google Tango, Microsoft HoloLens) or other 3D geometry reconstruction techniques [17, 25, 40].

Our work comprises two technical components: First, we design an effective optimization algorithm that optimizes reflector 3D shapes for a target wireless coverage. During this process, we represent a reflector shape as a parametric model [39] in computer graphics to ensure surface smoothness and in turn the feasibility of 3D fabrication. The shape optimization leverages a 3D wireless modeling to evaluate the effectiveness of a candidate shape and improve the shape iteratively. We guide a Simulated Annealing algorithm [28] using local gradient descent to sample the shape space more efficiently. We also extend our optimization to deal with multiple APs and jointly optimize their reflector shapes. Second, we develop an efficient modeling approach that uses 3D ray tracing to simulate radio signal propagation and signal’s interaction with objects in a 3D environment. We consider signal’s reflection, transmission, and diffraction through objects. For APs with multiple antennas, we also take into account the antenna location and orientation to trace radio signals accurately in the 3D space.

We 3D print optimized reflectors, test them with various Wi-Fi APs (including the latest 802.11ac AP) via signal and throughput measurements in two indoor settings. Our findings are as follows:

- Optimized reflectors correctly adjust signal distribution towards the target coverage. Resulting signal strength can decrease by up to 10 dB and increase by 6 dB, leading to throughput differences from -63.3% to 55.1%;
- Optimized reflectors coexist nicely with various Wi-Fi APs including MIMO APs (e.g., TP-Link AP and Netgear R7000). They allow multiple APs to collaboratively serve a region, or to confine each AP’s coverage to enhance security and reduce interference;
- The optimized reflector is relatively easy to place. Its efficacy is not sensitive to slight placement offsets, tolerating up to 10° offset in orientation and 10 cm offset in the distance to the AP;
- Given an environment model, our system computes an optimized reflector shape in 23 minutes on a laptop (2.2 GHz Intel Core i7).

Our work presents a low-cost, secure, and easy-to-configure approach that can coexist with directional communication via multi-antenna beamforming. Physical reflectors regulate signal distribution across regions at the macro level, while beamforming enables finer-grained signal enhancement at individual clients within the coverage. While we use Wi-Fi as an example, our approach can be generalized to other wireless bands (e.g., light, millimeter waves, acoustics). It can improve efficiency of diverse wireless networks in built environments, and potentially help in delivering higher-order services for buildings, e.g., occupancy detection, lighting control.

3 REFLECTOR SHAPE OPTIMIZATION

We optimize the reflector shape, aiming to generate a target wireless coverage for a given environment. We first present parameterizing the 3D geometry of a reflector, followed by our shape optimization procedure, as well as its extension to deal with multiple APs.

3.1 Representing the Reflector Shape

To represent a 3D surface, we seek a shape parameterization that can express a large space of feasible shapes and yet entail a low control degrees of freedom for the sake of computational performance. A naive solution is to represent a shape as a triangle mesh and optimize the positions of mesh vertices. However, this approach has a large number of optimization variables (i.e., the positions of mesh vertices). It results into an optimization problem in a high dimensional space, which is rather computationally expensive. Furthermore, the resulting shape might not be well-formed and thus cannot be fabricated in practice.

We overcome this challenge by leveraging the Non-uniform rational B-spline (NURBS) surface [39], a shape parameterization commonly used in computer graphics and engineering design [18]. The NURBS surface offers appealing properties: 1) it is flexible, supporting a large variety of shapes including standard analytical shapes such as spheres and free-form shapes; 2) it guarantees a smooth surface, facilitating the fabrication; and 3) it enables fine-grained control with low complexity using a small number of control points.

The NURBS surface is defined by NURBS curves. A NURBS curve consists of a set of weighted control points, a knot vector and its order. We aim to fit control points on the curve, which then determine the curve shape. The knot vector is a list of ascending numbers, defining where and how control points affect the NURBS
curve. By manipulating the knot vector, we can decide whether the curve passes through or passes by certain control points. The size of the knot vector is equal to the number of control points plus the order. The order defines the number of nearby control points that influence any given point on the curve.

A NURBS surface is calculated as the tensor product of two NURBS curves. Thus, it has two parametric directions \( (u, v) \) and two corresponding orders and knot vectors. For our purposes, we predefine its knot vectors and orders and then manipulate its shape by changing positions of the control points. A NURBS surface \( \Omega(u, v) \) is constructed as:

\[
\Omega(u, v) = \sum_{i=1}^{l} \sum_{j=1}^{w} R_{i,j}(u,v)P_{i,j},
\]

with

\[
R_{i,j}(u,v) = \frac{N_{i,n}(u)N_{j,m}(v)w_{i,j}}{\sum_{p=1}^{l} \sum_{q=1}^{w} N_{p,n}(u)N_{q,m}(v)w_{p,q}}
\]
as rational basis functions, where we have \( l \times w \) control points \( P_{i,j} \), and \( w_{i,j} \) is the corresponding weight. \( N_{i,n}(u) \) is the \( i \)th B-spline basis function of degree \( n \) [19]. In our model, a shape \( \Omega \) is defined by \( l \times w \) control points \( P_{i,j} \). We set their weights as 1, which is a common usage. Figure 1 illustrates two example NURBS surfaces with \( 4 \times 4 \) control points, where we lift the center control points to generate a concave shape on the left and then lift the four corner points to generate the shape on the right.

### 3.2 Optimizing the Reflector Shape

To search for the reflector shape optimized for a target coverage, we start with a flat plane as the reflector shape \( \Omega \) and then perturb \( \Omega \) over iterations. In each iteration, we evaluate the effectiveness of a candidate shape \( \Omega \) by the objective function \( F(\Omega) \), where \( F(\Omega) \) measures the difference between the desired coverage and the coverage \( C_{\Omega} \) resulting from reflector shape \( \Omega \). We estimate \( C_{\Omega} \) by running the 3D wireless modeling described in Section 4. Specifically, we divide the environment into small cells in uniform size (1 m × 1 m in our implementation). We apply the 3D wireless propagation modeling to predict signal strength at each cell’s center. Assuming \( M_a \) and \( M_c \) denote the areas where users aim to strengthen and weaken signals respectively, we compute \( F(\Omega) \) as:

\[
F(\Omega) = \sum_{i\in M_a\cup M_c} ||C_{\text{Target}}(i) - C_{\Omega}(i)||^2,
\]

where \( C_{\Omega}(i) \) is the signal strength in dBm at cell \( i \) after placing reflector shape \( \Omega \), and \( C_{\text{Target}}(i) \) is the target signal strength of cell \( i \). To derive \( C_{\text{Target}}(i) \), we first compute signal \( C(i) \), which is the estimated signal strength at cell \( i \) when no reflector is placed. We then add/subtract \( \delta \), which is the expected signal enhancement/reduction at cell \( i \). To determine \( \delta \), we tested different materials on their performance of signal enhancement and attenuation at distances from 1 to 3 meters. Results (Figure 5) show that the signal change is at most 15 dB. Thus we set \( \delta \) to 15 dB and write \( C_{\text{Target}}(i) \) as:

\[
C_{\text{Target}}(i) = \begin{cases} 
C(i) + \delta & \text{if } i \in M_a \\
C(i) - \delta & \text{if } i \in M_c
\end{cases}
\]

Here we use a cell-dependent target value \( C_{\text{Target}}(i) \), rather than a uniform signal upper and lower bound, because \( C_{\text{Target}}(i) \) defines an equal range \( (\delta) \) above or below \( C(i) \). As a result, a given amount of signal enhancement or reduction leads to the same amount of change in \( F(\cdot) \), regardless of the cell location. This, however, is no longer guaranteed if a uniform bound is used, because of the quadratic nature of \( F(\cdot) \). Thus, \( C_{\text{Target}}(i) \) ensures the optimization process is unbiased across cells. Finally, the optimization process searches for \( \Omega^*: \Omega^* = \arg\min_{\Omega} F(\Omega) \), where \( \Omega^* \) is the 3D reflector shape that leads to signal distribution best matching the target.

While the optimization problem appears standard, the search space is daunting and many local optima exist (Figure 2(a)). Simple local search methods such as hill climbing can easily be stuck at local optima. We need efficient algorithm to identify the global optimal. To achieve this goal, we consider simulated annealing (SA) [28], which allows the iterations to opportunistically escape from the current local search area even if the escape leads to an increase in the objective function. The escape likelihood \( p \) is determined by two parameters in the algorithm: current temperature \( T \) and the increase in the objective function. SA keeps examining candidate shapes until \( T \) reaches the minimal temperature \( T_0 \). When a candidate shape \( \Omega \) is examined, the current temperature is cooled at a rate \( r \). SA accepts \( \Omega \) if \( F(\Omega) \) is lower than the previous candidate. Otherwise, it accepts \( \Omega \) with a probability \( p \). \( p \) is adapted over iterations. In the beginning when \( T \) is higher, \( p \) is also higher so SA tends to explore other areas in the shape space. As \( T \) decreases to 0, \( p \) approaches 0 so that it gradually settles at an optimum.

However, SA can require a fairly large number of iterations as it randomly samples the search space. To achieve better results, we propose to guide SA’s iterations using gradient descent. The key idea is to consider characteristics of a local search area for determining the next candidate. Specifically, in each iteration of SA, instead of randomly generating a shape as the candidate, we apply gradient descent to seek the local minimum as the next candidate. Take the \( k \)th iteration as an example, we first generate a random shape \( \Omega_k \), then we calculate the shape gradient \( \nabla F(\Omega_k) \) of objective...
We now extend the above shape optimization to handle multiple APs. Each iteration in our search can be Accelerating the Search.

We classify APs into two types: 2) Non-Collaborative APs: APs that are deployed by different entities. Each AP serves users in its own pre-defined coverage region, without the knowledge nor any control of other APs.

For collaborative APs, we jointly optimize their reflector shapes so that the resulting signal coverage best matches the target. Here the signal coverage map is defined based on the strongest signal received at a location from all collaborative APs. Thus, let \( \Omega = (\Omega_1, \ldots, \Omega_M) \) denote a set of candidate reflector shapes for \( M \) collaborative APs, where \( \Omega_j \) is the reflector shape for AP \( j \). Then its objective function \( F(\Omega) \) is similar to Eq.(2):

\[
F(\Omega) = \sum_{i \in M \cup M_*} ||C_{Target}(i) - C_{\Omega}(i)||^2,
\]

where \( C_{\Omega}(i) \) is the signal strength at cell \( i \) after placing reflector shapes \( \Omega \) at all APs. \( C_{Target}(i) \) is computed following Eq.(3), but with \( C(i) \) as the signal received at cell \( i \) from the strongest AP. Thus the search is to seek the optimal set of shapes \( \Omega^\ast = \arg \min_{\Omega} F(\Omega) \). To jointly optimize \( M \) reflectors, we interleave the perturbation of each AP’s reflector shape across iterations. Specifically, in an iteration, we perturb only one AP’s reflector shape to seek its next candidate shape while fixing other APs’ reflector shapes, and then move on to perturbing the next AP’s reflector shape in the next iteration. Each iteration of the optimization procedure is similar to Algorithm 1. We omit the algorithm details in the interest of space.

For non-collaborative APs, each AP has its own pre-defined coverage region without the knowledge of other APs, thus each AP’s reflector shape is optimized separately following Algorithm 1. For non-collaborative APs operating on the same channel, they can interfere with one another if their coverage regions are nearby. The impact of interference can be minimized if the information (e.g., location, reflector shape) of other interfering APs is available to the shape optimization algorithm. We can estimate the interference at each cell and consider signal-to-interference ratio (SINR) as the target (Eq. (2)) for shape optimization. We leave it for future work.

### 4 EFFICIENT 3D WIRELESS MODELING

An essential part of our shape optimization is an efficient modeling that simulates wireless signal propagation in a given environment for evaluating the efficacy of a candidate reflector shape. Most existing models either fall far short in modeling accuracy [29, 36], or require expensive measurement or computation overhead. To achieve a better tradeoff, we choose 3D ray tracing for its best accuracy [26, 35, 53] and design schemes to speed up its computation. In particular, we choose the Shooting-and-Bouncing Ray (SBR) launching algorithm [21, 30, 43], which launches a number of rays from the transmitter and traces all their possible paths to reach a receiver. Next we describe the key steps of our modeling.

#### Ray Launching

We model each antenna of a Wi-Fi AP as a signal source\(^3\). To achieve accurate ray tracing, rays need to be uniformly spread from the transmitter, i.e., angles between any two adjacent rays are uniform. To do so, we use the geodesic sphere ray launching [51]. A geodesic sphere (Figure 3) is formed by tessellating faces of a regular polyhedron and extrapolating the intersection points on the surface of a sphere [27]. The geodesic vertices provide equivalent angular separation around the entire sphere [43]. Thus, we can place the transmitter at the sphere center and emit a ray to every geodesic vertex on the sphere to guarantee uniform

---

\(^3\)More antennas imply more signal sources and thus higher computation overhead in wireless modeling. They also impose more physical constraints to place the reflector...
Ray Tracing. We track each ray’s interaction with environmental objects. Given the wavelength of Wi-Fi signals, we consider three types of interactions (Figure 4(a)): transmissions (rays penetrate the objects), reflections (a ray is bounced over a smooth surface), and diffractions (a ray hitting an object edge is diffracted as a set of rays in a cone shape, Figure 4(b)). To model diffraction, we leverage the Uniform Theory of Diffraction (UTD) used by the fast-wave acoustics simulation in computer graphics [52]. It has also been applied in modeling RF propagation in buildings [37]. Similar to [24, 26], we do not consider wave phase as we average signal strengths in each measurement. To model wave phenomena like scattering since they have negligible impact on the resulting signal map [26]. We also do not consider the near-field effect, since we calculate signal strength at locations at least 4m away from the antenna, while the Fraunhofer distance [11] defining the near field is tens of centimeters in our setting. Each type of ray interaction contributes to additional energy loss of a ray, in addition to its signal degradation over distance. To integrate all these contributions, we choose a partition model [9, 26] to calculate each ray’s signal power at a receiver location. The model consists of four parts: 1) the signal degradation over distance, represented by the pathloss exponent $\alpha$; 2) the reflection attenuation, which is the product of the reflection coefficient $\beta$ and the number of reflections; 3) the transmission attenuation, which is the product of the transmission coefficient $\gamma$ and the number of times a ray penetrates obstacles; and 4) the diffraction attenuation, which is the product of the diffraction coefficient $\lambda$ and the number of diffractions. We do not consider multiple diffractions and reflection-diffraction [43].

Formally, let $P_i^j$ denote the power in dBm contributed by the $i^{th}$ ray of $j^{th}$ AP after traveling a distance of $d_i$ to reach a receiver, we can calculate $P_i^j$ as:

$$P_i^j = P_i^j - 10\alpha\log_10(d_i/d_0) - \beta N_{i,\text{ref}} - \gamma N_{i,\text{trans}} - \lambda N_{i,\text{diff}} - \beta' N_{i,\text{ref}}' - \gamma' N_{i,\text{trans}}'. \tag{6}$$

Fraunhofer distance is calculated as $2D^2/\lambda$, where $D$ is the largest physical linear dimension of the antenna and $\lambda$ is the wavelength.

Ray Reception. Finally, to calculate the received signal strength at a receiver location, we sum the power of each ray within the reception zone $Z$ of this receiver. Formally, let $P_i^j$ (in dBm) be the received power from AP $j$, we have $P_i^j = 10\log_10 \sum_{i \in Z} 10P_i^j/10$, where $P_i^j$ is the power contributed by ray $i$ from AP $j$ calculated by Eq. (6). We consider the reception zone as a sphere with radius of $d/\sqrt{3}$ centered at the receiver [42], where $d$ is the average radial angular separation between adjacent rays launched from the transmitter, and $d$ is the length of a ray’s propagation path to the receiver. The radius of the reception sphere considers the fact that rays are spread out as they propagate. Figure 4 shows the reception sphere for each ray, where ray2 travels the longest distance to reach receiver and thus has the largest reception sphere.

Speeding Up Ray Tracing. While offering higher accuracy, ray tracing incurs heavy computation, mainly because of calculating intersections of a large number of rays and triangle meshes. To speed up the ray tracing process, we index the triangle meshes with a KD-Tree [12]. We construct a KD-Tree of the bounding boxes containing these triangle meshes. For each ray, we first search the tree to identify the bounding boxes that the ray intersects. Only for the triangle meshes in those bounding boxes, we examine the ray-triangle intersection, which avoids many unnecessary intersection tests. For each ray-box and ray-triangle intersection test, we apply prior algorithms [22, 32] to improve the efficiency.

5 REFLECTOR FABRICATION

With the optimized shape $\Omega^*$, the last step is to realize it as a physical reflector. We represent $\Omega^*$ as its corresponding control points of the NURBS surface, calculate the coordinates of each mesh point based on Eq. (1), and store all mesh points in an .obj file. We
We evaluate our approach by testing optimized reflectors in two indoor scenes. We seek to understand its capability in affecting wireless signal distribution and throughput, implications on enhancing security and reducing interference, its sensitivity to reflector placement and size, and other performance microbenchmarks.

6.1 Experimental Setup

Indoor Scenes. We experiment two indoor scenarios with different room layouts: (a) workspace scenario: a 19 m × 13 m indoor area with a narrow (7.5-m long) hallway connecting a research lab and two offices; (b) home scenario: a 16 m × 12 m area where a spacious lobby (5.8 m × 5.1 m) is surrounded by three rooms. Figure 6(a) and Figure 7(a) show their floor maps, respectively. Although rooms are furnished in both scenes, the 3D environment models used in our shape optimization contain only walls and doors (we will evaluate the impact of including furniture in environment models in § 6.5). Experiments are conducted during working hours with moving users around (walking, working at their desks, or standing and talking to others). For the simplicity and feasibility of the user input, we assume the same material for objects in the environment. To consider heterogeneous materials, we can adapt the reflection, transmission and diffraction coefficients in Eq. (6) based on materials, and track what materials a ray has traveled through.

6.2 Efficacy of Optimized Reflector

We start by examining the overall efficacy of the optimized reflector in a single-AP setting. We consider a target coverage in Figure 6(a), where we mark areas with received signals to be strengthened by ticks and areas with signals to be weakened by crosses. We run our shape optimization algorithm to derive the optimized reflector shape, fabricate the reflector (20 cm × 20 cm in size), and place it around AP’s antennas. Figure 6(d) shows the optimized 3D shape, its estimated radiation pattern, and its placement. The radiation pattern is generated by simulating signal change at one meter away. For this target coverage, an antenna is behind the reflector and the others are in front of the reflector. We measure changes in the resulting RSS and throughput.

Impact on Signal Distribution. We collect the signal maps before and after placing the reflector around the AP. We also compare...
the results to that of a naive reflector shape (the concave shape used in anecdote experiments, Figure 6(b)). Figure 6(c) and (e) show the RSS change (in dB), where positive numbers indicate signal enhancements and negative numbers indicate signal declines. We observe that the optimized reflector correctly adjusts signals in all target areas, weakening signals in the hallway and room 2 by 10 dB while strengthening signals in other target areas by 6 dB. It achieves the goal by blocking an antenna that emits signals to the hallway and room 2 while reflecting the signals of the other two antennas towards room 1. The naive reflector, however, generates a simple radiation pattern that uniformly weakens signals in all areas in the back of the reflector, and thus fails to meet requirements of all target areas. The result demonstrates the necessity and efficacy of our optimization, which considers the indoor layout to customize the reflector shape and enables more flexible control.

A side effect of the optimized reflector is that in order to weaken signals in the hallway and room 2, it also slightly weakens the RSS in the right bottom of the lab. It is a sacrifice made by the shape optimization to reach an overall signal distribution better matching the target. As we further analyze signal change at individual cells, 83.1% of cells have their signals correctly strengthened or weakened. To further examine the overall efficacy of the optimized reflector, we deploy two APs in scene 2 and jointly optimize their reflector shapes for a target coverage in Figure 7(a). We measure the signal map before and after placing reflectors, where the RSS change in Figure 7(b). The two optimized reflectors successfully reduce signal strength in lobby by up to 10 dB and increase signals up to 6 dB in room 3, 4 and 5. Overall, 91% of cells have their signals correctly strengthened/weakened, demonstrating the overall efficacy of the optimized reflector.

**Impact on Throughput.** We further examine how signal-level changes translate into throughput differences at clients. We sample a few locations (marked as blue circles in Figure 6(a)) and measure the throughput at those locations before and after placing the reflector. In particular, we associate two laptops (MacBook Pro) with our AP. We fix the location of a laptop, while a user holds the other laptop walking around within each location to measure the throughput. We instrument one laptop to transmit 500-MB data to the other using the iperf utility and collect throughput statistics. We repeat the experiment for 10 rounds.

Figure 6(f) shows the percentage of throughput change under different APs with optimized reflectors. We also include error bars covering 90% confidence intervals. Overall throughput increases/decreases by up to 22.1% /36.7% in target areas. The throughput improvement at location 8 is small because its RSS is low, requiring a larger signal enhancement to switch to higher data rates. The throughput at location 9 slightly decreases because its RSS is slightly weakened by the reflector (Figure 6(e)). Most other locations in the lab experience improved throughput. Overall, the optimized reflector correctly adjusts throughput for 11 out of 12 locations. The result also shows that our reflectors can coexist nicely with MIMO APs (i.e., TP-Link AP and Netgear R7000).

### 6.3 Multi-AP Settings

We now move on to scenarios with multiple APs. As follows, we consider two types of APs described in § 3.3.

**Collaborative APs.** To evaluate the efficacy of jointly optimized reflectors, we deploy two APs in scene 2 and jointly optimize their reflector shapes for a target coverage in Figure 7(a). We measure the signal map before and after placing reflectors, where the RSS at a location is the signal from the stronger AP. We plot the signal change in Figure 7(b). The two optimized reflectors successfully reduce signal strength in lobby by up to 10 dB and increase signals up to 6 dB in room 3, 4 and 5. Overall, 91% of cells have their signals correctly strengthened/weakened. To further examine the impact on resulting bandwidth, we sample 9 locations (blue circles in Figure 7(a)) and plot in Figure 7(c) the throughput change brought by optimized reflectors. For 7 out of 9 locations, the throughput changes from -63.3% to 55.1%. Location 13 and 18 experience little change because of their minor signal changes (Figure 7(b)). Overall

---

6The numbers are slightly different from that in Figure 5 since the result here is measured at further distances and also affected by the environment.
the signal and throughput changes are notable for the majority of locations, demonstrating the efficacy of our joint optimization.

Non-Collaborative APs. For non-collaborative APs, we aim to confine each AP’s coverage. We examine the implications on security/privacy and interference reduction with optimized reflectors.

1) Implications on Security/Privacy: We set up two Netgear R7000 APs in scene 1 and mark each AP’s coverage region in Figure 8(a). We then fabricate reflectors for these APs to confine their coverage. We measure packet loss rates at sampled locations (marked as blue circles) before and after placing reflectors. We associate two laptops (MacBook Pro) with the same AP and instrument a laptop to transmit packets to the other using the iperf utility. Similarly to [45], we desire packet loss rates above 30% for locations outside an AP’s coverage region, as many TCP and UDP based applications [10, 41] require a packet loss rate below 25%.

Figure 8(b) plots packet loss rates when a receiver outside an AP’s region attempts to connect to this AP. Before placing any reflector, all locations have access to both APs. After placing optimized reflectors, we find that room2 (location 1 and 2) is unable to access the network of AP1 (50 - 60% packet loss rates), and locations at the lab (location 6, 7, and 8) can not access AP2. This demonstrates that optimized reflectors help confine Wi-Fi signal strength in the desired region. We also observe that for some locations outside an AP’s region, packet loss rate does not change much after placing the reflector, e.g., the packet loss rate of AP2 at location 9 is nearly 0% with or without the reflector. It is because location 9 is relatively close to AP2 and receives a strong signal from AP2 even with the reflector. The same holds for location 3, 4, and 5. To address this limitation, we plan in future work to include transmit power as another parameter in our model to control coverage more precisely.

2) Reducing Interference: To quantify the benefit on interference reduction, we examine Signal to Interference Noise Ratio (SINR) at locations in each AP’s coverage region. We reuse the setting in Figure 8(a) and compute the SINR at all locations. Figure 8(c) shows that reflectors boost the SINR for most locations by up to 13 dB. The SINR at location 9 barely changes because while AP2’s reflector weakens the interference, AP1’s reflector also weakens the signal at this location, resulting into little change in its SINR.

6.4 Reflector Placement and Size

In addition to the reflector shape, the reflector placement and size can also affect reflector’s efficacy. Next we examine system’s sensitivity to these factors. In following experiments, we use the optimized reflector in Figure 6(d) as an example.

Placement Offset. We first study the impact of orientation offset, which can occur during manual placement. In the experiment, the reflector (20 cm × 20 cm) faces room1 and room2 to enhance signals, which corresponds to the 0° orientation offset. We rotate the reflector from −30° to 30° in a counterclockwise manner with 5° interval. We then plot the average signal enhancement of interested locations in room1 and room2 in Figure 9(a). During the experiment, we observe some large signal variation at certain locations (location 10) when the orientation offset is within 10°, but the variation is only within 0.51 dB for room1 and 0.83 dB for room2, indicating that the reflector can tolerate small orientation offset. Orientation offset larger than 10° results in slow decrease in signal enhancement.
We then examine how the distance between the reflector and AP affects the performance. We fix the reflector’s orientation, vary its distance from 0 cm to 25 cm with 5-cm interval, and plot the average signal enhancement at room1 and room2 in Figure 9(b). We observe that offsets within 10 cm have negligible impact. Once the distance is above 10 cm, the signal enhancement starts to decrease. It is because as signals travel, they are further spread out with attenuated strength. Thus, a reflector further away from the AP reflects fewer signals and is less effective in affecting signal distribution.

**Reflector Size.** We also study the impact of reflector size on reflector’s ability to adjust signal distribution. A larger reflector reflects more signals and can be more effective, however its fabrication is harder and more costly. We aim to seek a proper size to achieve a good tradeoff. We fabricate the reflector in two sizes: 20 cm × 20 cm and 40 cm × 40 cm. Given that the height and width of all our APs are roughly 20 cm, a 20 cm × 20 cm reflector can cover all antennas. We place each reflector around the AP and measure the resulting RSS change at room1 and room2. As we compare the mean RSS change and the standard deviation for these two sizes, we observe negligible difference, indicating as long as the reflector covers all antennas, it needs not to be larger. This observation can be a guideline for determining reflector size for APs in other sizes.

### 6.5 Microbenchmarks

Finally, we examine the accuracy of our 3D wireless modeling and overall running time of the shape optimization.

**Accuracy of 3D Wireless Modeling.** Using scene 1 as an example, Figure 10 (a) and (b) plot CDFs of absolute RSS errors of our 3D wireless model (described in § 4), using measured RSS as ground truth. Figure 10 (a) is the result without any reflector, while Figure 10 (b) is for a concave shaped reflector placed around the AP. Overall, the mean RSS error of 3D wireless modeling is 3 dBm.

Furthermore, we compare our 3D modeling to the 2D modeling in a prior work [16]. We observe that 3D modeling notably lowers the tail of RSS errors. The maximal error of 2D modeling is 11 dBm and 16 dBm, with and without reflector respectively, while they are 8 dBm and 12 dBm for 3D modeling. 3D modeling outperforms 2D modeling because of more accurate characterization of signal interaction in the third dimension. We also include the results when 2D/3D wireless modeling uses a finer-grained environment model that includes main furniture (e.g., desks, sofas). We observe that for both 2D and 3D modeling, adding furniture leads to negligible difference in resulting accuracy in both scenarios. The results indicate that coarse-grained 3D environmental models are sufficient.

**Running Time.** We run our shape optimization algorithm on a MacBook Pro (2.2 GHz Intel Core i7) and record the time to generate an optimized shape for various target coverage requirements. We observe that the algorithm stabilizes after 23 minutes on average.

We further look into effectiveness of our speedup schemes: the Kd-tree used to speed up wireless modeling, the SPSA algorithm and multiple threads to speed up the search for optimized shape. Table 2 lists the running time of the optimization process when using either no speedup scheme, or only one speedup scheme, or all of them. Having 107 triangle meshes and 10K rays in the ray tracing model, we see that the Kd-tree accelerate around 1.6 times. For a complex model that has thousands of triangle meshes, the speedup of Kd-tree can be up to tens of times. Theoretically SPSA can reduce tens of time to calculate the gradient when we have 3×5 control points, however it only speeds up roughly 1.5 times, because the search for appropriate step size is another bottleneck. Multiple threads accelerate nearly 4 times. Together, they reduce the average running time from 207 minutes to 23 minutes.

<table>
<thead>
<tr>
<th>Scheme</th>
<th>No speedup</th>
<th>SPSA only</th>
<th>Kd-tree only</th>
<th>Threads only</th>
<th>Full speedup</th>
</tr>

</table>

**Table 2:** Running time of our shape optimization with and without speedup schemes (SPSA, Kd-Tree, and multiple threads).

### 7 RELATED WORK

**Configuring Wireless Coverage.** Prior works have optimized AP placement to improve signal reception in certain areas [35]. However, moving the AP to enhance one area would result into the decline of signal strength in other areas. Thus, such methods are constrained in their flexibility. Another method is to use directional APs to confine wireless coverage to a specified region [45]. However, this method needs multiple costly directional APs. Our approach works with a single AP without directional antennas.

As for the use of reflectors, recent work [20, 49, 50] has studied reusing walls to reflect radio waves and control signal propagation. This method, however, relies on smart walls made of special materials and requires infrastructure-level changes. Similarly, a latest work [23] examined placing multiple metal plates in the environment to enhance wireless performance of a single AP. This approach also requires nontrivial changes in the environment by installing reflectors likely in large sizes. In contrast, our approach uses only a small reflector at the AP, is applicable in any environment, and supports multiple APs. Additionally, [23] optimizes reflector locations, whereas our work optimizes reflector shape. Another prior work [16] studied the feasibility of using fabricated reflector to control wireless coverage. We advance this prior work in multiple fronts: a more sophisticated shape model, a more efficient shape optimization and extension to multiple APs, 3D wireless modeling, and extensive indoor experiments with optimized reflectors.

**Directional Antennas.** Directional antennas increase signal gain in a chosen direction and thus improve spatial reuse [8, 14, 15, 33, 38, 47, 48]. Researchers have studied steerable-beam antenna’s link quality outdoors [15] and its directionality indoors [14]. Its directionality greatly decreases due to rich multipath effects [8, 14, 34]. In comparison, we consider the influence of indoor layout when optimizing reflector shape. Besides, low-cost directional antennas (e.g., microstrip antennas [8], sectorized antennas [48]) only provide limited simple patterns. Our reflector is low-cost and flexible in radiation patterns.
Directional antennas often rely on multi-antenna beamforming, which electronically adjusts an array of omni-antennas to form narrow beams and maximize the signal strength for one or multiple users [5, 44]. Despite its superior performance, it has three main limitations. First, it cannot provide physical security, as it only enhances client’s signal reception and cannot take into account client’s location information (i.e., whether the client is inside the authorized location or not). As a result, it can end up forming a beam towards an attacker outside the authorized area. Second, it is more costly than our solution as it requires multiple antennas, each with a separate RF chain. Finally, it imposes expensive measurement overhead by collecting real-time Channel State Information (CSI).

8 CONCLUSION AND FUTURE WORK

We studied the design of a low-cost, 3D-fabricated reflector to customize wireless coverage. We demonstrated the efficacy of optimized reflectors with reflector prototypes and indoor experiments.

We summarize the limitations of our study and plans for future work. First, our current reflectors are in static shapes. Thus, upon substantial changes in the environment (e.g., removal/addition of walls), the reflector shape needs to be re-calculated and fabricated. Minor furniture changes have minimal impact on the resulting coverage, as shown in Figure 10, thus not requiring to replace the reflector. In the future, we will study reflectors made of transformable materials, enabling the reflector to automatically adapt its shape upon major changes. Second, the wavelength of Wi-Fi signals limits reflector’s ability to reflect and block signals (Figure 5). Thus, changes on RSS and throughput have been moderate. Moving forward, we will examine higher frequency bands such as millimeter waves and visible light, where reflectors can block and reflect signals more effectively and cause more significant change in signal distribution. Finally, we will explore augmenting directional antennas with optimized reflectors and analyze their interplay.
