Abstract

This package provides a lightweight mechanism for making C++ objects persistent. Each persistent object must derive from the IR::Node class and implement simple read and write member functions that fill in and write its fields to XML input and output streams.

The XML reading facility is built on top of James Clark’s standard expat XML parser, and first builds an in-memory tree of the XML document before traversing it to build a tree of IR::Node-derived objects.

Self-referential (cyclic) data structures are supported by writing each object at most once and including references in the XML file where necessary.

1 IR Nodes

1.1 The Node Class

All nodes in the IR are derived from IR::Node. Each such class has a single static member called _ that holds its name, which the className method returns. The XML writing methods use this method to obtain the element name for each object.

The XMLostream class uses the write method to send the contents of the object’s fields to the XML output stream. Similarly, XMListream fills the object’s fields with data from an XML input stream.

```
class Node {
    friend class XMLostream;
    friend class XMListream;
    protected:
        virtual void read(XMListream &) {}
        virtual void write(XMLostream &) const {}
    public:
        static IR::Class _;
        virtual const std::string className() const { return _; }
};
```

Each class in the IR must register itself with the Class class to ensure it can be written and read. This is done with a macro:

```
IRCLASS(Node);
```

The definitions for the _ field and className are standard and tedious to type, so other files may use the IRCLASSDEFS macro:

```
# define IRCLASSDEFS
public:
    static IR::Class _;
    virtual const std::string className() const { return _; }
```
1.2 An example user-defined Node

class MyNode : public Node {
    IRCLASSDEFS; // Class name machinery: sets public:
    Node *f1;
    string f2;
    vector<MyNode*> f3;

    protected:
    void read(XMListream &r) {
        Node::read(r); // Read fields of parent class
        r >> f1 >> f2 >> f3; // Read our fields
    }
    void write(XMLostream &w) const {
        Node::write(w); // Write parent class
        w << f1 << f2 << f3; // Write our fields
    }
};

/* In a .cpp file */
IRCLASS(MyNode);

1.3 The Class class

While writing XML, the system needs to know the name of the class of each object, and during reading, needs a way to create an IR object given only its name. The Class class performs this feature.

The class has a static map called classmap that keeps a pointer to a zero-argument function that creates a new IR node object for each class name. The newNodeByName method uses this to create a new Node object (usually, something derived from Node).

The other part of the class is a static string that holds the name of the class. The Node::className method implicitly uses the cast-to-const-string operator to retrieve the name of the class.

\[
\text{(Class class)} \equiv \\
// Information for the classes in the IR: a string naming each, 
// and a map giving the constructor for each class
\text{class Class} \{ \\
    \text{typedef Node *(*createfunc)}(); \\
    \text{typedef std::map<std::string, createfunc> createfuncmap}; \\
    \text{static createfuncmap *classmap}; \\
\text{public:} \\
    \text{Class(std::string, createfunc);} \\
    \text{static Node *newNodeByName(const std::string);} \\
\text{private:} \\
\]
const std::string _className;
public:
    operator const std::string () { return _className; }
};

As mentioned above, each Node has a static Class member that holds its name. The constructor for this takes both a string naming the class and the address of a no-argument function (Class::createfunc) for constructing it. The IRCLASS macro does this automatically using the constructor template, which generates such a function automatically.

\begin{Verbatim}
\texttt{IRCLASS macro} \equiv
\texttt{\# define IRCLASS(s) IR::Class s::_ = IR::Class( \#s, IR::constructor<s> )}
\end{Verbatim}

\begin{Verbatim}
\texttt{constructor template} \equiv
\texttt{template<class T> Node* constructor() \{ return new T(); \}}
\end{Verbatim}

The constructor for Class saves the name of the class and enters it into the map along with the constructor function.

A pointer is used for classmap to insure the correct order of initialization. The map must be constructed before the Class constructor enters anything into it, but C++ does not provide any such guarantees. Instead, the pointer to classmap is initialized to 0 (such constant data is typically initialized before the program starts in the data section) and the constructor (somewhat wastefully) checks the pointer each time a new class is registered.

\begin{Verbatim}
\texttt{Class constructor} \equiv
\texttt{Class::createfuncmap *Class::classmap = 0;}

\texttt{Class::Class(const std::string s, Class::createfunc f) : _className(s) \{}
    \texttt{if (!classmap) classmap = new createfuncmap();}
    \texttt{(*classmap)[s] = f;}
\texttt{\}}
\end{Verbatim}

The newNodeByName method uses the classmap map to construct an object whose class name is the given string. For this to work, the class must derived from Node and the type registered by a call to the CLASS constructor (i.e., by using IRCLASS).

\begin{Verbatim}
\texttt{Class::newNodeByName} \equiv
\texttt{Node * Class::newNodeByName(const std::string s) \{}
    \texttt{assert(classmap);}
    \texttt{createfuncmap::iterator i = classmap->find(s);}
    \texttt{if (i != classmap->end()) \{}
        \texttt{createfunc cf = (*i).second;}
        \texttt{return (*cf());}
    \texttt{else \{}
        \texttt{throw Error("Unknown class " + s);}
    \texttt{\}}
\texttt{\}}
\end{Verbatim}
2 Writing XML

Writing XML is fairly easy. The class encapsulates an `ostream` and provides `<<` operators that behave like those for standard streams. So a Node’s `write` method can be defined as shown in Section 1.2.

This class is meant to be used as follows:

```cpp
Node *root;

/* Build a (possibly cyclic) graph of Nodes under root ... */

XMLostream w(std::cout);
w & root;
```

Writing a Node object starts a depth-first search of all its fields. To avoid writing duplicate copies of the same object, the ID map maintains a positive integer identifier for each written object. When the DFS encounters an object it has already written, a reference to that object’s ID is written, rather than the information in the node itself.

```cpp
class XMLostream {
  typedef std::map<const Node *, unsigned int> idmap;
  idmap ID;

  unsigned int nextID;
  std::ostream &o;

public:
  XMLostream(std::ostream &oo) : nextID(0), o(oo) {}  
  XMLostream& operator <<(const Node&);
  XMLostream& operator <<(const Node *);
  XMLostream& operator <<(const std::string);
  XMLostream& operator <<(int);
  XMLostream& operator <<(bool);
  XMLostream& operator <<(std::vector<
  XMLostream& operator <<(std::map output)
  XMLostream vector output
  XMLostream map output
  
};
```
The following operator, which writes a single Node-derived object, is fairly simple: it just identifies the type of the object and writes its contents. These objects are meant to be fields of other objects, and it is assumed that nothing ever points directly to them.

\[
\langle \text{XMLostream Node output} \rangle \equiv
\text{XMLostream} & \text{XMLostream::operator } \ll (\text{const Node } \& n)
\{
  o << "<" << n.className() << '>' << std::endl;
  n.write(*this); // usually a recursive call
  o << "</" << n.className() << "" << std::endl;
  return *this;
\}
\]

The following operator, which writes a Node object referred to by a pointer, does most of the heavy lifting. Null pointers are written as a single XML element called NULL. If this XMLostream has already written the given object, an XML element called Ref is written whose id attribute is the integer identifier of the object.

Otherwise, the operator writes the given object by writing an element named by the object’s type (obtained by calling Node::className). To write the fields of the object, it calls the write method on the given Node. This virtual method is expected to use the & operator to write the objects in its fields to this stream (see Section 1.2).

\[
\langle \text{XMLostream Node pointer output} \rangle \equiv
\text{XMLostream} & \text{XMLostream::operator } \ll (\text{const Node } * n)
\{
  if (n == NULL) {
    o << "<NULL/>" << std::endl;
  } else {
    idmap::iterator i = ID.find(n);
    if (i != ID.end()) {
      // Already written this Node: leave a placeholder
      o << "<Ref id="" << (*i).second << ""/>" << std::endl;
    } else {
      o << "<" << n->className() << " id="" << nextID << ""/>" << std::endl;
      ID[n] = nextID;
      nextID++;
      n->write(*this); // usually a recursive call
      o << "</" << n->className() << "">" << std::endl;
    }
  }
  return *this;
\}
Strings are written by simply sending their output to the output stream. Empty strings are written as an **EmptyString** element because the reader otherwise discards empty strings.

\[\langle \text{XMLostream string output} \rangle \equiv \text{XMLostream\& XMLostream::operator<<(const std::string s)} \]

```cpp
{  
o << "<S>";  
  for (std::string::const_iterator i = s.begin() ; i != s.end() ; i++ )  
    switch (*i) {  
    case '&': o << "&amp;"; break;  
    case '<': o << "&lt;"; break;  
    case '>': o << "&gt;"; break;  
    case '\': o << "&apos;"; break;  
    case '"': o << "&quot;"; break;  
    default: o << *i; break;  
    }  
o << "</S>\n";  
  return *this;  
}
```

Integers are written as text in an **Int** element.

\[\langle \text{XMLostream int output} \rangle \equiv \text{XMLostream\& XMLostream::operator<<(int i)} \]

```cpp
{  
o << "<Int>" << i << "</Int>\n";  
  return *this;  
}
```

A Boolean is written as either a **BoolTrue** or **BoolFalse** element.

\[\langle \text{XMLostream bool output} \rangle \equiv \text{XMLostream\& XMLostream::operator<<(bool b)} \]

```cpp
{  
  if (b) o << "<BoolTrue/>";  
  else o << "<BoolFalse/>";  
  return *this;  
}
```

The contents of a vector is written by writing each of the objects it contains followed by a single **EOV** (End-of-vector) XML element.

\[\langle \text{XMLostream vector output} \rangle \equiv \text{template <class T> XMLostream\& XMLostream::operator<<(const std::vector<T\*>& v)} \]

```cpp
{  
  typename std::vector<T\*>::const_iterator i;  
  for ( i = v.begin() ; i != v.end() ; i++ ) (*this) << *i;  
  o << "<EOV/>" << std::endl;  
  return *this;  
}
```
The contents of a map is written out a sequence of keys and values followed by an EOM (End-of-map) XML element.

\[
\langle \text{XMLostream map output} \rangle \equiv \\
\text{template <class } K, \text{ class } V> \\
\text{XMLostream} & \text{ operator } <<(\text{const std::map}<K, V> &m) \{ \\
\text{typename std::map}<K, V>::\text{const} \_\text{iterator} \ i; \\
\text{for} ( \ i = m.\text{begin}(); \ i \ != m.\text{end}(); \ i++ ) \\
\text{(*this) } << (\ast i).\text{first} \ << (\ast i).\text{second}; \\
\text{o } << "<\text{EOM/}>>" \ << \text{std::endl}; \\
\text{return } \text{this;}
\}
\]
3 Reading XML

Reading XML is fairly complex. This system uses the *expat* XML parser\(^1\) to first build an internal tree representing the contents of the XML file, then walks this tree, creating Node-derived objects based on the name of each element, then using each Node’s `read` method to “fill in” each object’s fields.

This two-phase process is awkward, but the (fairly standard) “event-driven” interface of the *expat* parser almost demands it. Basically, you give *expat* a pointer to a function that it calls each time it encounters an element. While the structure of XML guarantees elements are encountered in a top-down order, *expat* insists that you return from this function before it will parse further, so it is difficult to implement a traditional top-down parser.

The public interface to the class consists of a constructor that takes a standard `istream` and overloads of the `>>` operator that parses an XML element into a variable passed by reference. The class is meant be used as follows:

```cpp
Node *root;

XMLStream r(std::cin);
r >> root;
```

3.1 The XMLNode class

The XMLNode class holds the parsed XML tree that the & operators later read. Each node has a name, a body containing its character data, which is often ignored, a map holding the node’s attributes, and pointers to its first child and next sibling.

```cpp
struct XMLNode {
    std::string name;
    std::string body;

    typedef std::map<const std::string, const std::string> attrmap;
    attrmap attrs;

    XMLNode *first;
    XMLNode *next;

    XMLNode() : first(0), next(0) {}

    ~XMLNode() { delete first; delete next; }

    void print();
};
```

The print method pretty-prints the tree for debugging.

```cpp
void XMLNode::print() {
    std::cout << '<' << name;
    for (attrmap::iterator j = attrs.begin() ; j != attrs.end(); j++)
        std::cout << ' ' << (*j).first << "=" << (*j).second;
    std::cout << '>
    std::cout << body;
    if (first) first->print();
    std::cout << '</"" """"""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""""`
3.2 Parsing XML with expat

The *expat* parser is invoked in the constructor of `XMListream` to construct a tree of `XMLNode` objects. The functions whose names start with `XML_` are all part of `expat`. The constructor creates a parser, tell it to call the static methods `startElement`, `endElement`, and `charData` with a pointer to itself, then repeatedly fills `buffer` with characters from the input stream and parses it.

```cpp
XMListream::XMListream(std::istream &i) {
    root = lastsibling = NULL;
    XML_Parser p = XML_ParserCreate(NULL);
    if (!p) throw Error("Couldn't create parser");

    XML_SetElementHandler(p, startElement, endElement);
    XML_SetCharacterDataHandler(p, charData);
    XML_SetUserData(p, (void *) this);

    do {
        static const size_t SIZE = 8192;
        char buffer[SIZE];

        i.read(buffer, SIZE);
        if (i.bad()) throw Error("Read error");
        if (!XML_Parse(p, buffer, i.gcount(), i.eof())) {
            std::ostringstream ost;
            ost << "XML parsing error at line " << XML_GetCurrentLineNumber(p) << ':' << XML_ErrorString(XML_GetErrorCode(p));
            throw Error(ost.str());
        }
    } while (!i.eof());

    XML_ParserFree(p);
    if (!parents.empty()) throw Error("Non-empty stack.");

    // root->print(); // For debugging
    current = root;
}
```
The static methods `startElement`, `endElement`, and `charData` are called by the expat parser when it encounters the start or end of an XML element (e.g., `<MyNode>` and `</MyNode>`) or character data appearing between such markers.

During this process, the three methods maintain the stack of `XMLNode` objects that define the path through the tree to the element currently being parsed. The top of the `parents` stack is the `XMLNode` whose body is currently being parsed, and the pointer `lastsibling` points to its most-recent-added child, which starts out NULL right after a new element is encountered.

The `attachSibling` method attaches the given node at the bottom of the current tree of `XMLNodes`, defined by the `parents` stack. Just after a new node is created, `lastsibling` is NULL and the method attaches the node as the first child at the top of the stack. After that, it simply sets the `next` pointer of the most-recently-added child.

```cpp
void XMListream::attachSibling(XMLNode *n) {
    if (root == NULL) root = n;
    if (!lastsibling) {
        if (!parents.empty()) parents.top()->first = n;
    } else
        lastsibling->next = n;
    lastsibling = n;
}
```

The `startElement` method creates a new `XMLNode`, calls `attachSibling` to attach it to the tree, then pushes it onto the `parent` stack and clears the last sibling pointer so `attachSibling` will next attach its first child.

```cpp
void XMListream::startElement(void *rr, const char *name, const char **attrs) {
    XMListream *r = static_cast<XMListream*>(rr);
    XMLNode *newNode = new XMLNode();
    newNode->name = name;
    while (*attrs) {
        newNode->attrs.insert( std::make_pair(*attrs,*(attrs+1)) );
        attrs += 2;
    }
    r->attachSibling(newNode);
    r->parents.push(r->lastsibling);
    r->lastsibling = NULL;
}
The `endElement` method restores the `lastsibling` pointer that was last pushed onto the `parents` stack by `startElement`.

```
(XMLListream endElement) ≡
void XMListream::endElement(void *rr, const char *)
{
  XMListream *r = static_cast<XMListream*>(rr);
  // discard the topmost sibling; we'll go back to where we were.
  r->lastsibling = r->parents.top();
  r->parents.pop();
}
```

The `charData` method takes the non-null-terminated character string passed from `expat` (hence the `len` argument) and appends it to the body of the most-recently-created `XMLNode`, if there is one. Appending is necessary because `Expat` may call this multiple times within the same block of text if it contains entities such as `<`.  

```
(XMLListream charData) ≡
void XMListream::charData(void *rr, const XML_Char *ss, int len)
{
  XMListream *r = static_cast<XMListream*>(rr);
  std::string s(ss, len);
  if (!(r->parents.empty()))
    r->parents.top()->body += s;
}
3.3 Parsing XMLNode trees

Once the XMLstream constructor runs and builds an XMLNode tree from the XML file, the getNextNode method steps through the tree in a depth-first order under the control of the IR Node’s read methods. During this process, the current pointer points to the node in the XMLNode tree currently being read, and the parents stack is used to track the current path from the root.

```cpp
Node *XMLstream::getNextNode()
{
    if (!current) throw Error("Expecting an element, found nothing");
    Node *n;
    XMLNode::attribmap::iterator idit = current->attrs.find("id");
    if (current->name == "NULL") { // NULL pointer
        n = NULL;
    }
    else if (current->name == "Ref") { // Reference to existing object
        if (idit == current->attrs.end())
            throw Error("Ref node without id attribute");

        nodemap::iterator ni = nodeofid.find((*idit).second);
        if (ni == nodeofid.end())
            throw Error("Ref to undefined node id " + (*idit).second);
        n = (*ni).second;
    }
    else { // Normal object
        std::string name = current->name;
        n = Class::newNodeByName(name);
        if (idit != current->attrs.end())
            nodeofid[(*idit).second] = n;
        parents.push(current);
        current = current->first;
        n->read(*this); // Fill in the node's fields from this stream
        if (current != NULL) throw Error("excess elements under " + name);
        current = parents.top();
        parents.pop();
    }
    current = current->next;
    return n;
}
```
\(\text{XMLListream Node input}\) ≡
\[
\text{template <class N> XMListream& operator >>}(N &n) \{ \\
\quad \text{if ( current->name != std::string(N::_:)) // Check name of this class} \\
\quad \text{throw Error("Unexpected element " + current->name); } \\
\quad \text{parents.push(current); } \\
\quad \text{current = current->first; } \\
\quad \text{n.read(*this); // Fill in the object's fields} \\
\quad \text{if (current != NULL) } \\
\quad \quad \text{throw Error("excess elements for " + std::string(N::_:)); } \\
\quad \text{current = parents.top(); } \\
\quad \text{parents.pop(); } \\
\quad \text{current = current->next; } \\
\quad \text{return *this;} \\
\}
\]

The pointer version of the \& operator reads a Node using getNextNode and uses dynamic_cast to cast it to the type of the referenced object, provided we didn’t find a NULL pointer.

\(\text{XMLListream Node ptr input}\) ≡
\[
\text{template <class T> XMListream& operator >>}(T* &f) \{ \\
\quad \text{Node *n = getNextNode(); } \\
\quad \text{f = (n != NULL) ? dynamic_cast<T*>(n) : NULL; } \\
\quad \text{if (!f && n) throw Error("Unexpected element " + n->className()); } \\
\quad \text{return *this;} \\
\}
\]

The string version of the >> operator looks for either an EmptyString element or an XMLNode of type Text.

\(\text{XMLListream string input}\) ≡
\[
\text{XMListream& XMListream::operator >>}(\text{std::string &s}) \{ \\
\quad \text{if (!current) throw Error("Expecting text before end of element");} \\
\quad \text{if (current->name != \"S\")} \\
\quad \quad \text{throw Error("Expecting text, found " + current->name); } \\
\quad \text{s = current->body; } \\
\quad \text{current = current->next; } \\
\quad \text{return *this;} \\
\}
\]

\(\text{XMLListream int input}\) ≡
\[
\text{XMListream& XMListream::operator >>}(\text{int &i}) \{ \\
\quad \text{if (!current) throw Error("Expecting an Int");} \\
\quad \text{if (current->name == \"Int\")} \\
\quad \quad \text{std::istringstream iss(current->body);} \\
\quad \quad \text{iss >> i;} \\
\quad \text{else} \\
\quad \quad \text{throw Error("Expected Int, found " + current->name); } \\
\quad \text{current = current->next; } \\
\quad \text{return *this;} \\
\}
\]
\langle XMLListream\ bool\ input\ ⟩ \equiv
\begin{verbatim}
XMLListream& XMLListream::operator >> (bool &i) {
    if (!current) throw Error("Expecting BoolTrue or BoolFalse");
    if (current->name == "BoolTrue") i = true;
    else if (current->name == "BoolFalse") i = false;
    else throw Error("Expecting BoolTrue or BoolFalse");

    current = current->next;
    return *this;
}
\end{verbatim}

The vector version of the >> operator reads objects using the >> operator until it encounters an EOV element, which it discards.

\langle XMLListream\ vector\ input\ ⟩ \equiv
\begin{verbatim}
template <class T> XMLListream& operator >> (std::vector<T> &v) {
    while (current && current->name != "EOV") {
        T value;
        (*this) >> value;
        v.push_back(value);
    }
    if (!current) throw Error("vector ended without EOV");
    current = current->next; // Skip the EOV Element
    return *this;
}
\end{verbatim}

The map version of the >> operator reads using getNextNode until it encounters an EOM element, which it discards.

\langle XMLListream\ map\ input\ ⟩ \equiv
\begin{verbatim}
template <class K, class V> XMLListream& operator >> (std::map<K, V> &m) {
    while (current && current->name != "EOM") {
        K key;
        V value;
        (*this) >> key >> value;
        m.insert( typename std::map<K,V>::value_type(key, value) );
    }
    if (!current) throw Error("map ended without EOM");
    current = current->next; // Skip the EOM Element
    return *this;
}
\end{verbatim}
4 Miscellany

4.1 The Error class

Error is a simple class holding a string thrown as an exception for parsing errors.

\[
\begin{align*}
\text{Error class} & \equiv \\
& \text{struct Error} \\
& \quad \text{std::string s;} \\
& \quad \text{Error(std::string ss) : s(ss)} \\
& \end{align*}
\]

4.2 IR.hpp and IR.cpp

All these classes are defined in the IR namespace.

\[
\begin{align*}
\text{IR.hpp} & \equiv \\
& \text{#ifndef _IR_HPP} \\
& \quad \text{# define _IR_HPP} \\
& \quad \text{# include <expat.h>} \\
& \quad \text{# include <string>} \\
& \quad \text{# include <map>} \\
& \quad \text{# include <stack>} \\
& \quad \text{# include <vector>} \\
& \quad \text{# include <iostream>} \\
& \end{align*}
\]

\[
\begin{align*}
& \text{namespace IR {} \\
& \quad \text{class Node;} \\
& \quad \text{class XMListream;} \\
& \quad \text{class XMLostream;} \\
& \end{align*}
\]

\[
\begin{align*}
& \text{Error class} \\
& \text{Class class} \\
& \text{Node class} \\
& \text{XMLstream class} \\
& \text{XMLNode class} \\
& \text{XMLstream class} \\
& \text{constructor template} \\
& \end{align*}
\]

\[
\text{#endif}
\]
```cpp
#include "IR.hpp"
#include <expat.h>
#include <iostream>
#include <sstream>
#include <cassert>

namespace IR {

    // Node class info
    // XMLostream Node pointer output
    // XMLostream Node output
    // XMLostream string output
    // XMLostream int output
    // XMLostream bool output

    // XMLNode::print

    // XMListream constructor
    // XMListream string input
    // XMListream int input
    // XMListream bool input
    // XMListream getNextNode
    // XMListream attachSibling
    // XMListream startElement
    // XMListream endElement
    // XMListream charData

    // Class constructor
    // Class::newNodeByName
}
```
