Parsing and Syntax Trees

Parsing decides if the program is part of the language. Not that useful: we want more than a yes/no answer.

Like most, ANTLR parsers can include actions: pieces of code that run when a rule is matched.

Top-down parsers: actions executed during parsing rules.

Bottom-up parsers: actions executed when rule is “reduced.”

Actions

In a top-down parser, actions are executed during the matching routines.

Actions can appear anywhere within a rule: before, during, or after a match.

`rule { /* before */ };
A { /* during */ } B
| C D { /* after */ };

Bottom-up parsers restricted to running actions only after a rule has matched.

Implementing Actions

Nice thing about top-down parsing: grammar is essentially imperative.

Action code simply interleaved with rule-matching.

Easy to understand what happens when.

Implementing Actions

expr returns [int r] { int a; r=0; }
: r=mexpr ("+" a=mexpr { r += a; } )* EOF ;
mexpr returns [int r] { int a; r=0; }
: r=atom ("*" a=atom { r *= a; } )* ;
atom returns [int r] { r=0; }
: i:INT
{ r = Integer.parseInt(i.getText()); };

Actions

Simple languages can be interpreted with parser actions.

class CalcParser extends Parser;

eexpr returns [int r] { int a; r=0; }
: r=mexpr ("+" a=mexpr { r += a; } )* EOF ;

eexpr returns [int r] { int a; r=0; }
: r=mexpr ("*" a=mexpr { r *= a; } )* EOF ;

eexpr returns [int r] { int a; r=0; }
: expr() {
  int r; int a; r=0;
  r=mexpr();
  while (LA(1)==PLUS) {
    match(PLUS);
    a=mexpr();
    r += a;
  }
  match(Token.EOF_TYPE);
  return r;
}

Actions

Usually, actions build a data structure that represents the program.

Separates parsing from translation.

Makes modification easier by minimizing interactions.

Allows parts of the program to be analyzed in different orders.

Actions

Bottom-up parsers can only build bottom-up data structures.

Children known first, parents later.

→ Constructor for any object can require knowledge of children, but not of parent.

Context of an object only established later.

Top-down parsers can build both kinds of data structures.

What To Build?

Typically, an Abstract Syntax Tree that represents the program.

Represents the syntax of the program almost exactly, but easier for later passes to deal with.

Punctuation, whitespace, other irrelevant details omitted.
Abstract vs. Concrete Trees

Like scanning and parsing, objective is to discard irrelevant details.

E.g., comma-separated lists are nice syntactically, but later stages probably just want lists.

AST structure almost a direct translation of the grammar.

Implementing ASTs

Most general implementation: ASTs are \( n \)-ary trees.

Each node holds a token and pointers to its first child and next sibling:

```
Parent
+--- Last Sibling
     +--- Node
     |    +--- First Child
```

```
Example of AST structure

```
The Obvious Way to Build ASTs

```java
class ASTNode {
    ASTNode( Token t ) { ... }
    void appendChild( ASTNode c ) { ... }
    void appendSibling( ASTNode c ) { ... }
}
```

```java
stmt returns [ASTNode n]
    : 'if' p=expr 'then' t=stmt 'else' e=stmt {
        n = new ASTNode(new Token("IF"));
        n.appendChild(p);
        n.appendChild(t);
        n.appendChild(e);
    };
```

The Obvious Way

Putting code in actions that builds ASTs is traditional and works just fine.

But it’s tedious.

Fortunately, ANTLR can automate this process.

Building an AST Automatically with ANTLR

```java
class TigerParser extends Parser;
options {
    buildAST=true;
}
```

By default, each matched token becomes an AST node.

Each matched token or rule is made a sibling of the AST for the rule.

After a token, `^` makes the node a root of a subtree.

After a token, `^` prevents an AST node from being built.

Automatic AST Construction

Running

```java
class CalcParser extends Parser;
options { buildAST=true; }
expr : mexpr ('+' mexpr)* EOF ;
mexpr : atom ('*' atom)* ;
atom : INT ;
on
2*3+4*5+6
``` gives

```latex
2 \ast 3 \ast 4 \ast 5 \ast 6 \EOF
```

AST Construction with Annotations

Running

```java
class CalcParser extends Parser;
options { buildAST=true; }
expr : mexpr ('+'^ mexpr)* EOF! ;
mexpr : atom ('*'^ atom)* ;
atom : INT ;
on
2*3+4*5+6
``` gives

```latex
+ \ast 6
+ \ast 3\ast 4\ast 5
```

Choosing AST Structure

Designing an AST Structure

Sequences of Things

Comma-separated lists are common

```java
int gcd(int a, int b, int c)
``` args : 

```latex
(" ( arg (".\) arg)* )? ")
```

A concrete parse tree:

```latex
\begin{itemize}
  \item Many unnecessary nodes
  \item Branching suggests recursion
  \item Harder for later routines to get the data they want
\end{itemize}
```

Sequences of Things

Better to choose a simpler structure for the tree.

Punctuation irrelevant; build a simple list.

```java
int gcd(int a, int b, int c)
``` args : 

```latex
(" ( ! arg (".\) arg)* )? ")"!
```````
```
```
```
```
```
```latex
ARGS
```
What's going on here?

\[
\text{args : "(! ( arg (","! arg)* )? "!)}
\]

Rule generates a sequence of arg nodes.
Node generation suppressed for punctuation (parenthesis, commas). Action uses ANTLR's terse syntax for building trees.

```
{ \#args = \#([ARGS], args); }
```

"set the args tree to a new tree whose root is a node of type ARGS and whose child is the old args tree"

---

Removing Unnecessary Punctuation

Punctuation makes the syntax readable, unambiguous. Information represented by structure of the AST

Things typically omitted from an AST

- Parentheses
  - Grouping and precedence/associativity overrides
- Separators (commas, semicolons)
  - Mark divisions between phrases
- Extra keywords
  - While-do, if-then-else (one is enough)

---

Additional Grouping

Tiger allows mutually recursive definitions only in uninterrupted sequences:

```
let
  function f1() = ( f2() ) /* OK */
  function f2() = ( ... )
in ... end
```

```
let
  function f1() = ( f2() ) /* Error */
  var foo := 42 /* splits group */
  function f2() = ( ... )
in ... end
```

---

Grouping

Identifying and building sequences of definitions a little tricky in ANTLR.

Obvious rules

```
defs : ( func | vars | types )* ;
defs : ( func | vars | types )* ;
```

are ambiguous: Maximum-length sequences or minimum-length sequences?

---

Grouping

Convenient to group sequences of definitions in the AST. Simplifies later static semantic checks.

```
let
  function f1() = ( ... )
  function f2() = ( ... )
  var foo := 42
in ... end
```

```
defs : ( func | vars | types )* ;
defs : ( func | vars | types )* ;
```

are ambiguous: Maximum-length sequences or minimum-length sequences?

---

Grouping

Hint: Use ANTLR's greedy option to disambiguate this.

The greedy flag decides whether repeating a rule takes precedence when an outer rule could also work.

```
string : (dots)* ;
dots : ( options greedy=true; : ".")+ ;
```

When faced with a period, the second rule can repeat itself or exit.

---

The Greedy Option

Setting greedy true makes "dots" as long as possible

```
string : (dots)* ;
dots : ( options greedy=true; : ".")+ ;
```

Setting greedy false makes each "dots" a single period

```
string : (dots)* ;
dots : ( options greedy=false; : ".")+ ;
```

---

How Many Types of Tokens?

Since each token is a type plus some text, there is some choice.

Generally, want each "different" construct to have a different token type.

Different types make sense when each needs different analysis.

Arithmetic operators usually not that different.

For the assignment, you need to build a node of type "BINOP" for every binary operator. The text indicates the actual operator.
Walking ASTs

ANTLR can build “tree parsers” as easily as token parsers.

Much simpler: tree structure is already resolved.

Simple recursive walk on the tree.

Matches are sufficient, not exact.

(Cheaper to implement.)

#( A B ) also matches the larger tree
#( A #(B C) D )

ANTLR with ANTLR

class CalcParser extends Parser
expr : mexpr ("+" mexpr)* ;
mexpr : atom ("*" atom)* ;
atom : INT | "(" expr ")" ;

class CalcWalker extends TreeParser
expr returns [int r]
{ int a,b; r=0; }
| #("+" a=expr b=expr) { r = a + b; }
| #("*" a=expr b=expr) { r = a * b; }
| i:INT { r = parseInt(i.getText()); }
;

This walker only has one rule: grammar had three.
Fine: only structure of tree matters.

Comments on walking ASTs

Optional clauses can cause trouble.
Place them at the end.

stmt
: #("if" expr stmt (stmt)?) // OK
| #("do" (stmt)? expr) // Bad
;

First rule works: can easily decide if there is another child.
Second rule does not: not enough lookahead.

Comments on walking ASTs

Lists of undefined length can also cause trouble

//funcdef
: #("func" ID (arg)* stmt)
;

Does not work because the tree walker does not look ahead.

Solution: use a subtree

funcdef
: #("func" #("args" (arg)*) stmt)
;

The placeholder resolves the problem.

Walking ASTs with ANTLR

class CalcParser extends Parser
expr : mexpr ("+" mexpr)* ;
mexpr : atom ("*" atom)* ;
atom : INT | "(" expr ")" ;

class CalcWalker extends TreeParser
expr returns [int r]
{ int a,b; r=0; }
| #("+" a=expr b=expr) { r = a + b; }
| #("*" a=expr b=expr) { r = a * b; }
| i:INT { r = parseInt(i.getText()); }
;

The highlighted line says

Match a tree #( ... )

With the token "+" at the root

With two children matched by expr

(Store their results in a and b)

When this is matched, assign a + b to the result r.

Walking ASTs with ANTLR

I have supplied an AST walker that will serve as the specification for the Tiger AST.

The walker contains no actions, but will report a “syntax error” if supplied with an erroneous tree.
The Tiger Language

The little language we're going to compile for this class.
Taken from Appel, *Modern Compiler Implementation in Java*. 
Language reference manual on class web site: read it.

The let Expression

Things only get interesting with the let expression.

Syntax:

\[
\text{let declaration-list in expr-seq end}
\]

Idea: declarations in declaration-list are visible to the expr-seq.

\[
\text{let}
\begin{align*}
& \text{function sqr(x:int) = x * x} \\
& \text{in} \\
& \text{sqr(5)}
\end{align*}
\text{end}
\]

Declarations

\[
\text{let}
\begin{align*}
& \text{type intArray = array of int} \\
& \text{type point = ( x : int, y : int )} \\
& \text{type dot = point} \\
& \text{var pi := 31415} \\
& \text{var zeros : intArray := intArray [10] of 0} \\
& \text{function sqr(x:int) = x * x} \\
& \text{function cube(x:int) : int = x * x * x} \\
& \text{in} \\
& \text{0}
\end{align*}
\text{end}
\]

Comments

Comments begin and end as in C/Java: /* */
Comments may nest, so this is /*/**/ ignored */
Comments are often the hardest parts of a scanner.
Make sure to test them carefully.
Read the ANTLR documentation's discussion of comments.

String Constants

"Enclosed by double-quotes"
"May include escapes, e.g., newline \n"
"Other escapes: decimal ASCII \013"
"Multi-
\line string constants"

ANTLR scanners can change text as it's being scanned.
Use this to implement the escapes.

Grammar

Grammar given in the language reference manual is ambiguous.

Enough additional rules are given (associativity, precedence) to disambiguate it.

Doing this a big part of the assignment.

Grammatical Idiosyncrasies

The arithmetic operators + - * / associate left-to-right as usual.

The comparison operators = < <= > >= do no associate.

\[ a < b = c \] is illegal, but \((a < b) = c\) is.
Ambiguities?
The syntax for creating an empty array
\[ \text{type-id [ expr ] of expr} \]
looks a lot like the syntax for subscripting
\[ \text{value [ expr]} \]
Use ANTLR’s facilities for syntactic predicates for this.
\[
\text{stat: } \begin{align*}
\text{list } \text{"="} & \Rightarrow \text{list } \text{"="} \text{ list} \\
\text{list} & ;
\end{align*}
\]
The first rule says “try to match a list followed by =. If this works, proceed.”

Rewriting Trees
Much of compiling is refining and simplifying:
Discarding unnecessary information
Reducing high-level things to low-level ones
How to implement this depends on the representation.
Trees are fairly natural: replace one or more children.
ANTLR tree walkers can do semi-automatically.

Rewriting Trees with ANTLR
Next, disable automatic rewriting for the + operator and add a manual copy.
Adding ! before a subrule disables AST generation for that subrule.
Tree generation is like that in parsers.

Rewriting Trees with ANTLR
Finally, check for the \(x+0\) case.

Rewriting Trees with ANTLR
In the parser, \text{buildAST=true} adds rules that automatically builds an AST during parsing.
In a tree walker, \text{buildAST=true} adds code that automatically makes a copy of the input tree.
This is actually useful because you can selectively disable it and generate your own trees.

Rewriting Trees with ANTLR
Every binary operator should be represented with a the single token type BINOP.
The text of this token distinguishes the operator.
Fortunately, you can change the type of a token without changing its text:
\[
\text{ex: } \begin{align*}
\text{"foo"} & \{ \text{ex.setType(BINOP)}; \} ; \\
\end{align*}
\]

Rewriting Trees with ANTLR
An example: Replace \(x+0\) with \(x\).
First, make a copying TreeParser:

Rewriting Trees with ANTLR
A complete example:

Rewriting Trees with ANTLR
Examples of Tree Rewriting
This was incomplete: should do 0+x case, too.
General constant folding: replace constant arithmetic expressions with their results.
Must do this carefully: watch for overflow, imprecision.
Tricky to do correctly for integers, virtually impossible for floating-point.
Cross-compilation problem: how do you know the floating-point unit on your target machine behaves exactly like the one where you're compiling?

Examples of Tree Rewriting
Change logical operators && and || to if-then statements.

```c
if (a && b && c || d && e) { ... }
if (a) {
  if (b)
    if (c)
      goto Body;
  else if (d)
    if (e) {
      Body: ...
    }
}
```
You'll do this in the second assignment.

Examples of Tree Rewriting
Dismantle loops into gotos.

```c
while (a < 3) {
  printf("a is \%d", a);
  a++;
}
```
Becomes

```c
goto Continue;
Again:
  printf("a is \%d", a);
  a++;
Continue:
  if (a < 3) goto Again;
```
