A Closer Look Classification

Linear Decision Boundary

Assume binary classification y= {-1,+1} (What happens in multi-class case?) *g* = decision boundary

d=1 case: $g(x) = w_1 x + w_0 = 0$

general: $g(\vec{x}) = \vec{w} \cdot \vec{x} + w_0 = 0$

f = linear classifier

$$f(\vec{x}) := \begin{cases} +1 & \text{if } g(\vec{x}) \ge 0\\ -1 & \text{if } g(\vec{x}) < 0 \end{cases}$$

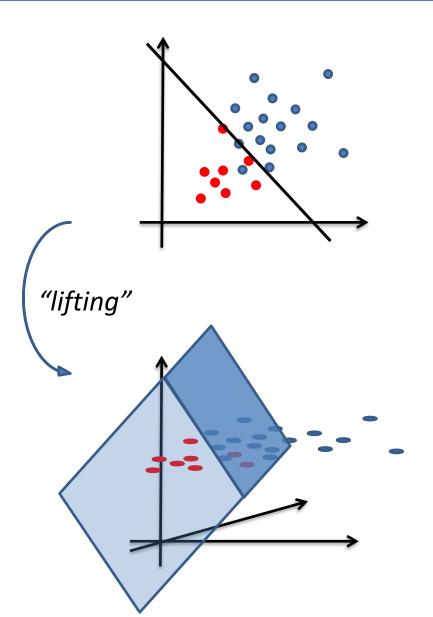

= sign $(\vec{w} \cdot \vec{x} + w_0)$

of parameters to learn in \mathbf{R}^d ?

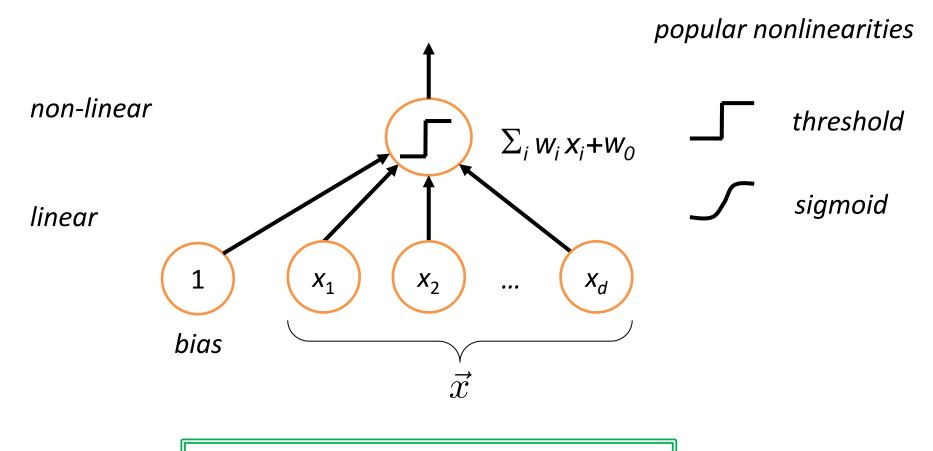

Dealing with w_o

$$g(\vec{x}) = \vec{w} \cdot \vec{x} + w_0$$
$$= \underbrace{\begin{pmatrix} \vec{w} \\ w_0 \end{pmatrix}} \cdot \underbrace{\begin{pmatrix} \vec{x} \\ 1 \end{pmatrix}}_{\textit{bias}} \textit{bias}$$
$$\vec{w}' \quad \vec{x}'$$

$$g(\vec{x}') = \vec{w}' \cdot \vec{x}'$$
 homogeneous

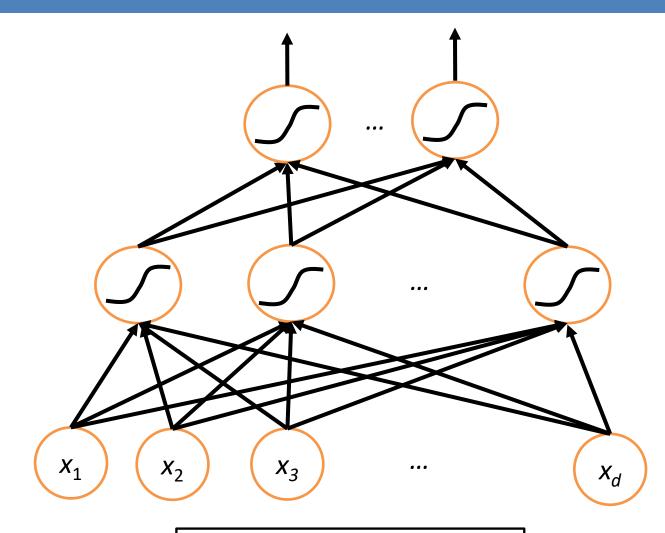

The Linear Classifier

A basic computational unit in a neuron

Can Be Combined to Make a Network

Amazing fact: Can approximate any smooth function!

An artificial neural network

How to Learn the Weights?

Given labeled training data (bias included): $(\vec{x}_1, y_1), (\vec{x}_2, y_2), \dots (\vec{x}_n, y_n)$ Want: \vec{w} , which minimizes the training error, i.e.

$$\arg\min_{\vec{w}} \frac{1}{n} \sum_{i=1}^{n} \mathbf{1} \left[\operatorname{sign}(\vec{w} \cdot \vec{x}_i) \neq y_i \right]$$
$$= \arg\min_{\vec{w}} \sum_{\substack{x_i \\ \text{s.t.} y_i = +1}} \mathbf{1} \left[\vec{x}_i \cdot \vec{w} < 0 \right] + \sum_{\substack{x_i \\ \text{s.t.} y_i = -1}} \mathbf{1} \left[\vec{x}_i \cdot \vec{w} \ge 0 \right]$$

How do we minimize?

• Cannot use the standard technique (take derivate and examine the stationary points). Why?

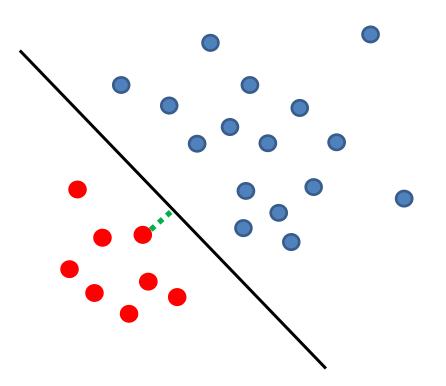

Unfortunately: NP-hard to solve or even approximate!

Can we approximate the weights if we make reasonable assumptions?

What if the training data is **linearly separable**?

Linear Separability

Say there is a **linear** decision boundary which can **perfectly separate** the training data

distance of the closest point to the boundary (margin γ) Given: labeled training data $S = (\vec{x}_1, y_1), (\vec{x}_2, y_2), \dots (\vec{x}_n, y_n)$

Want to determine: is there a \vec{w} which satisfies $y_i(\vec{w} \cdot \vec{x}_i) \ge 0$ (for all *i*) *i.e., is the training data linearly separable?*

Since there are d+1 variables and |S| constraints, it is possible to solve efficiently it via a (constraint) optimization program. (How?)

Can find it in a much **simpler** way!

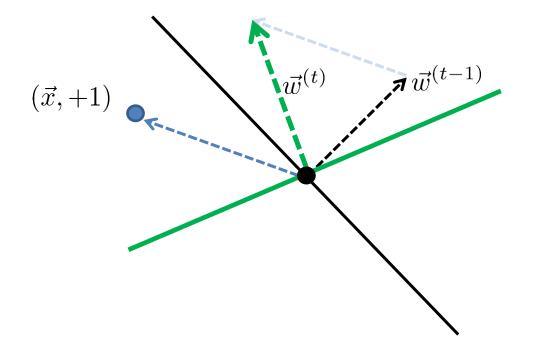

The Perceptron Algorithm

Given: labelled training data $S = (\vec{x}_1, y_1), (\vec{x}_2, y_2), \dots (\vec{x}_n, y_n)$

$$\begin{aligned} \text{Initialize } \vec{w}^{(0)} &= \mathbf{0} \\ \text{For t} &= \mathbf{1}, \mathbf{2}, \mathbf{3}, \dots \\ \text{If exists } (\vec{x}, y) \in S \text{ s.t. } \operatorname{sign}(\vec{w}^{(t-1)} \cdot \vec{x}) \neq y \\ \vec{w}^{(t)} \leftarrow \begin{cases} \vec{w}^{(t-1)} + \vec{x} & \text{if } y = +1 \\ \vec{w}^{(t-1)} - \vec{x} & \text{if } y = -1 \end{cases} &= \vec{w}^{(t-1)} + y\vec{x} \end{aligned}$$

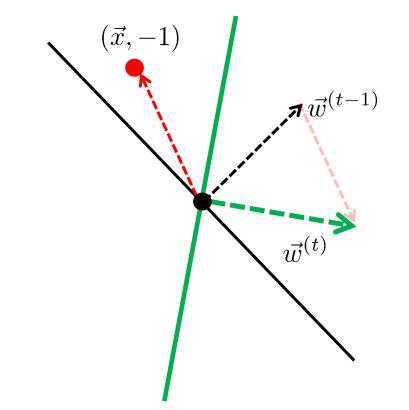

(terminate when no such training sample exists)

Perceptron Algorithm: Geometry

 $\operatorname{sign}(\vec{w}^{(t-1)} \cdot \vec{x}) \neq +1$ $\vec{w}^{(t)} \leftarrow \vec{w}^{(t-1)} + \vec{x}$ $\operatorname{sign}(\vec{w}^t \cdot \vec{x}) = +1$

Perceptron Algorithm: Geometry

 $\operatorname{sign}(\vec{w}^{(t-1)} \cdot \vec{x}) \neq -1$

$$\vec{w}^{(t)} \leftarrow \vec{w}^{(t-1)} - \vec{x}$$

$$\operatorname{sign}(\vec{w}^t \cdot \vec{x}) = -1$$

Input: labelled training data $S = (\vec{x}_1, y_1), (\vec{x}_2, y_2), \dots (\vec{x}_n, y_n)$

$$\begin{aligned} \text{Initialize } \vec{w}^{(0)} &= \mathbf{0} \\ \text{For t} &= \mathbf{1}, \mathbf{2}, \mathbf{3}, \dots \\ \text{If exists } (\vec{x}, y) \in S \text{ s.t. } \operatorname{sign}(\vec{w}^{(t-1)} \cdot \vec{x}) \neq y \\ \vec{w}^{(t)} \leftarrow \begin{cases} \vec{w}^{(t-1)} + \vec{x} & \text{if } y = +1 \\ \vec{w}^{(t-1)} - \vec{x} & \text{if } y = -1 \end{cases} &= \vec{w}^{(t-1)} + y\vec{x} \end{aligned}$$

(terminate when no such training sample exists)

Question: Does the perceptron algorithm terminates? If so, when?

Perceptron Algorithm: Guarantee

Theorem (Perceptron mistake bound):

Assume there is a (unit length) \vec{w}^* that can separate the training sample S with margin γ

Let R = $\max_{\vec{x} \in S} \|\vec{x}\|$

Then, the perceptron algorithm will make at most $T := \left(\frac{R}{\gamma}\right)^2$ mistakes.

Thus, the algorithm will terminate in T rounds! umm... but what about the generalization or the test error?

Proof

Key quantity to analyze: How far is $\vec{w}^{(t)}$ from \vec{w}^* ?

Suppose the perceptron algorithm makes a mistake in iteration t, then

$$\vec{w}^{(t)} \cdot \vec{w}^* = (\vec{w}^{(t-1)} + y\vec{x}) \cdot \vec{w}^*$$
$$\geq \vec{w}^{(t-1)} \cdot \vec{w}^* + \gamma$$

$$\begin{aligned} \|\vec{w}^{(t)}\|^2 &= \|\vec{w}^{(t-1)} + y\vec{x}\|^2 \\ &= \|\vec{w}^{(t-1)}\|^2 + 2y(\vec{w}^{(t-1)} \cdot \vec{x}) + \|y\vec{x}\|^2 \\ &\leq \|\vec{w}^{(t-1)}\|^2 + R^2 \end{aligned}$$

Proof (contd.)

for all iterations t

$$\vec{w}^{(t)} \cdot \vec{w}^* \geq \vec{w}^{(t-1)} \cdot \vec{w}^* + \gamma$$
$$\|\vec{w}^{(t)}\|^2 \leq \|\vec{w}^{(t-1)}\|^2 + R^2$$

So, after T rounds

$$T\gamma \le \vec{w}^{(T)} \cdot \vec{w}^* \le \|\vec{w}^{(T)}\| \|\vec{w}^*\| \le R\sqrt{T}$$

Therefore: T

$$\Gamma \leq \left(\frac{R}{\gamma}\right)^2$$

What Good is a Mistake Bound?

 It's an upper bound on the number of mistakes made by an *online* algorithm on an arbitrary sequence of examples

i.e. no i.i.d. assumption and not loading all the data at once!

• Online algorithms with small mistake bounds can be used to develop classifiers with good generalization error!

Other Simple Variants on the Perceptron

Voted perceptron

Average perceptron

Winnow

Linear classification simple,

but... when is real-data (even approximately) linearly separable?

What about non-linear decision boundaries?

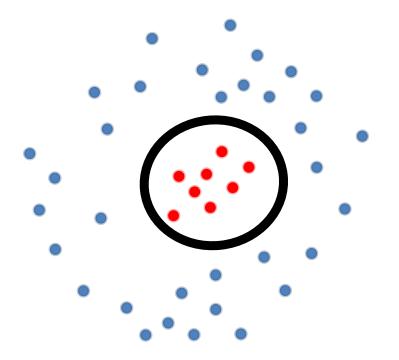

Non linear decision boundaries are common:

Generalizing Linear Classification

Suppose we have the following training data:

d=2 case:

 $g(\vec{x}) = w_1 x_1^2 + w_2 x_2^2 + w_0$

say, the decision boundary is some sort of ellipse

e.g. circle of radius r: $w_1 = 1$ $w_2 = 1$ $w_0 = -r^2$

n boundary *not linear in* \vec{x} !

separable via a circular decision boundary

But g is Linear in some Space!

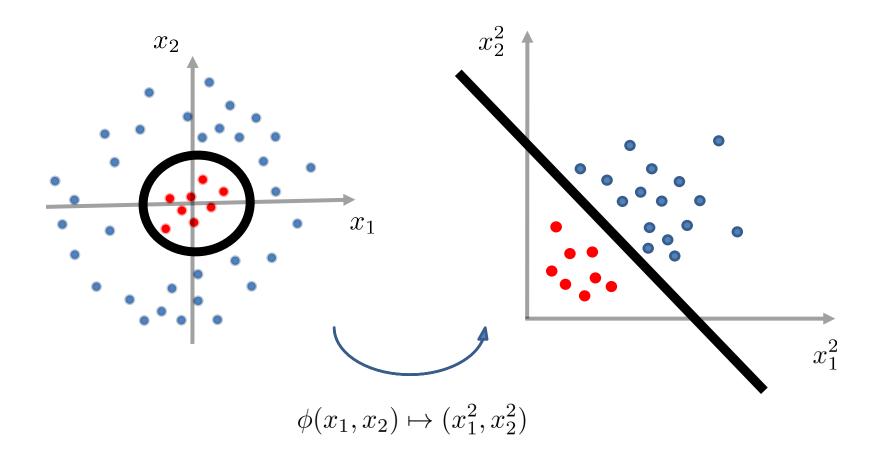

$$g(\vec{x}) = w_1 x_1^2 + w_2 x_2^2 + w_0 \qquad \text{non linear in } x_1 \& x_2$$
$$= w_1 \chi_1 + w_2 \chi_2 + w_0 \qquad \text{linear in } \chi_1 \& \chi_2 !$$

So if we apply a feature transformation on our data:

$$\phi(x_1, x_2) \mapsto (x_1^2, x_2^2)$$

Then *g* becomes linear in ϕ - transformed feature space!

Feature Transformation Geometrically

Feature Transform for Quadratic Boundaries

R² case: (generic quadratic boundary)

$$g(\vec{x}) = w_1 x_1^2 + w_2 x_2^2 + w_3 x_1 x_2 + w_4 x_1 + w_5 x_2 + w_0$$
$$= \sum_{p+q \le 2} w^{p,q} x_1^p x_2^q$$

feature transformation:

$$\phi(x_1, x_2) \mapsto (x_1^2, x_2^2, x_1 x_2, x_1, x_2, 1)$$

R^{*d*} case: (generic quadratic boundary)

$$g(\vec{x}) = \sum_{i,j=1}^{d} \sum_{p+q \le 2} w_{i,j}^{p,q} x_i^p x_j^p$$

This captures all pairwise interactions between variables

feature transformation:

 $\phi(x_1, \dots, x_d) \mapsto (x_1^2, x_2^2, \dots, x_d^2, x_1 x_2, \dots, x_{d-1} x_d, x_1, x_2, \dots, x_d, 1)$

Theorem:

Given *n* distinct points $S = \vec{x}_1, \vec{x}_2, \dots \vec{x}_n$

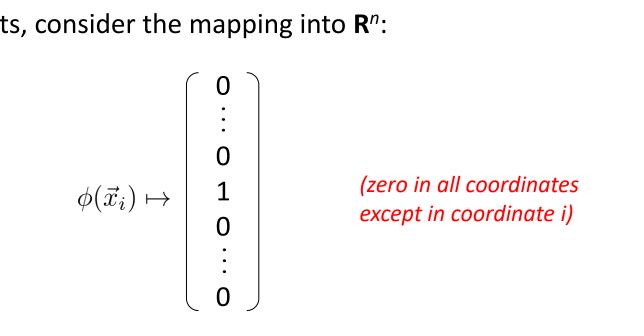

there exists a feature transform such that for *any* labelling of *S* is linearly separable in the transformed space!

(feature transforms are sometimes called the Kernel transforms)

the proof is almost trivial!

Given *n* points, consider the mapping into \mathbf{R}^n :

Then, the decision boundary induced by linear weighting $\vec{w}^* = \begin{bmatrix} y_1 \\ \vdots \\ y_2 \end{bmatrix}$ perfectly separates the input data!

Transforming the Data into Kernel Space

Pros:

Any problem becomes **linearly separable**!

Cons:

What about computation? Generic kernel transform is typically $\Omega(n)$

Some useful kernel transforms map the input space into **infinite dimensional space**!

What about model complexity?

Generalization performance typically degrades with model complexity

The Kernel Trick (to Deal with Computation)

Explicitly working in generic Kernel space $\phi(\vec{x}_i)$ takes time $\Omega(n)$

But the dot product between two data points in kernel space can be computed relatively quickly

 $\phi(\vec{x}_i) \cdot \phi(\vec{x}_j)$ can compute fast

Examples:

- quadratic kernel transform for data in \mathbb{R}^d explicit transform $O(d^2)$ $\vec{x} \mapsto (x_1^2, \dots, x_d^2, \sqrt{2x_1x_2}, \dots, \sqrt{2x_{d-1}x_d}, \sqrt{2x_1}, \dots, \sqrt{2x_d}, 1)$ dot products O(d) $(1 + \vec{x}_i \cdot \vec{x}_j)^2$
- RBF (radial basis function) kernel transform for data in \mathbb{R}^d *explicit transform* infinite dimension! $\vec{x} \mapsto ((2/\pi)^{d/4} \cdot \exp(-\|\vec{x} - \alpha\|^2))_{\alpha \in \mathbb{R}^d}$ dot products O(d) $\exp(-\|\vec{x}_i - \vec{x}_j\|^2)$

The trick is to perform classification in such a way that it **only accesses the data** in terms of **dot products** (so it can be done quicker)

Example: the `kernel Perceptron'

$$\begin{array}{ll} \textit{Recall:} & \vec{w}^{(t)} \leftarrow \vec{w}^{(t-1)} + y\vec{x} \\ \textit{Equivalently} & \vec{w} = \sum_{k=1}^{n} \alpha_k y_k \vec{x}_k & \alpha_k = \textit{\# of times mistake was made on } \textbf{x}_k \end{array}$$

Thus, classification becomes

$$f(\vec{x}) := \operatorname{sign}(\vec{w} \cdot \vec{x}) = \operatorname{sign}\left(\vec{x} \cdot \sum_{k=1}^{n} \alpha_k y_k \vec{x}_k\right) = \operatorname{sign}\left(\sum_{k=1}^{n} \alpha_k y_k (\vec{x}_k \cdot \vec{x})\right)$$

Only accessing data in terms of dot products!

The Kernel Trick: for Perceptron

classification in original space:

$$f(\vec{x}) = \operatorname{sign}\left(\sum_{k=1}^{n} \alpha_k y_k (\vec{x}_k \cdot \vec{x})\right)$$

If we were working in the transformed Kernel space, it would have been

$$f(\phi(\vec{x})) = \operatorname{sign}\left(\sum_{k=1}^{n} \alpha_k y_k \left(\phi(\vec{x}_k) \cdot \phi(\vec{x})\right)\right)$$

Algorithm:

Initialize
$$\vec{\alpha} = 0$$

For t = 1,2,3,..., T
If exists $(\vec{x}_i, y_i) \in S$ s.t. $\operatorname{sign}\left(\sum_{k=1}^n \alpha_k y_k \left(\phi(\vec{x}_k) \cdot \phi(\vec{x}_i)\right)\right) \neq y_i$
 $\alpha_i \leftarrow \alpha_i + 1$

implicitly working in non-linear kernel space!

The Kernel Trick: Significance

 $\sum \alpha_k y_k \big(\phi(\vec{x}_k) \cdot \phi(\vec{x}) \big)$

dot products are a measure of similarity

Can be replaced by any userdefined measure of similarity!

So, we can work in any user-defined non-linear space **implicitly without** the potentially heavy computational cost

What We Learned...

- Decision boundaries for classification
- Linear decision boundary (linear classification)
- The Perceptron algorithm
- Mistake bound for the perceptron
- Generalizing to non-linear boundaries (via Kernel space)
- Problems become linear in Kernel space
- The Kernel trick to speed up computation
