        Logic Programming (Prolog) Next lecture

int gcd(int a, int b)
{
  while (a != b) {
    if (a > b) a -= b;
    else b -= a;
  }
  return a;
}

int gcd(int a, int b)
{
  while (a != b) {
    if (a > b) a -= b;
    else b -= a;
  }
  return a;
}

```

Text file is a sequence of characters

Lexical Analysis Gives Tokens

```

int gcd(int a, b)
{
    while (a != b)
        if (a > b) a -= b;
        else b -= a;
    }
    return a;
}

```

A stream of tokens. Whitespace, comments removed.

Parsing Gives an AST

```
    }  
    return a;  
}
```

Semantic Analysis Resolves Symbols

The parse tree diagram illustrates the binding of variables in the given C-like code. Red lines connect variable names to their definitions:

- 'a' is defined at two levels: once as the left argument of a division operator ('arg / arg') and once as the left operand of a comparison operator ('int a > int b').
- 'b' is defined at three levels: once as the right argument of a division operator ('arg / arg'), once as the right operand of a comparison operator ('int a > int b'), and once as the right operand of an assignment operator ('int a = int b;').
- 'int' is defined at four levels: once as the type of 'a' and 'b' ('int a', 'int b'), once as the type of the arguments ('int a', 'int b'), once as the type of the condition ('int a > int b'), and once as the type of the loop ('int a != int b').
- 'seq' and 'return' are terminal symbols representing sequence and return statements.
- 'if' is a terminal symbol representing an if-else statement.
- 'while' is a terminal symbol representing a while loop.
- '=' is a terminal symbol representing an assignment operator.
- '>' is a terminal symbol representing a greater-than comparison operator.
- '!=:' is a terminal symbol representing a not-equal comparison operator.
- '/' is a terminal symbol representing a division operator.

Types checked; references to symbols resolved

Translation into 3-Address Code

Generation of 80386 Assembly

```

L0:    sne    $1,   a,   b          gcd:    pushl %ebp           % Save frame pointer
       seq    $0,   $1,   0          movl %esp,%ebp
       btrue $0,   L1             % Load a from stack

|idealized assembly language w/ infinite registers

```

Describing Tokens

Alphabet: A finite set of symbols

Examples: $\{0, 1\}$, $\{A, B, C, \dots, Z\}$, ASCII, Unicode

String: A finite sequence of symbols from an alphabet

Examples: ϵ (the empty string), Stephen, $\alpha\beta\gamma$

Language: A set of strings over an alphabet

Examples: \emptyset (the empty language), $\{1, 11, 111, 1111\}$, all English words, strings that start with a letter followed by any sequence of letters and digits

Operations on Languages

Let $L = \{\epsilon, wo\}$, $M = \{\text{man, men}\}$

Concatenation: Strings from one followed by the other

$L.M = \{\text{man, men, woman, women}\}$

Union: All strings from each language

$L \cup M = \{\epsilon, wo, \text{man, men}\}$

Kleene Closure: Zero or more concatenations

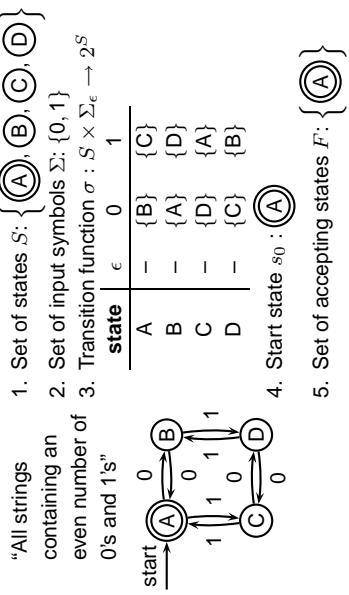

$M^* = \{\epsilon, M, MM, MMM, \dots\} = \{\epsilon, \text{man, men, manman, menmen, menmen, manmamman, manmanmen, manmenman, ...}\}$

Regular Expressions over an Alphabet Σ

A standard way to express languages for tokens.

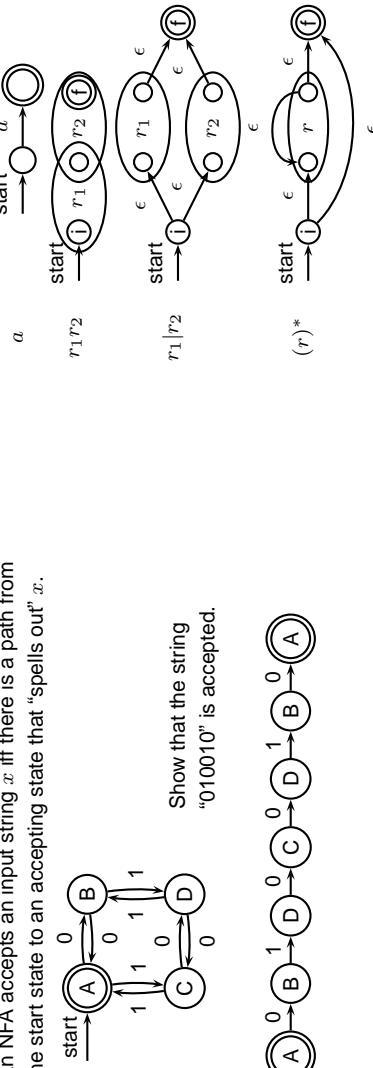

1. ϵ is a regular expression that denotes $\{\epsilon\}$
2. If $a \in \Sigma$, a is an RE that denotes $\{a\}$
3. If r and s denote languages $L(r)$ and $L(s)$,
 - $(r)|(s)$ denotes $L(r) \cup L(s)$
 - $(r)(s)$ denotes $\{tu : t \in L(r), u \in L(s)\}$
 - $(r)^*$ denotes $\cup_{i=0}^{\infty} L^i$ ($L^0 = \emptyset$ and $L^i = LL^{i-1}$)

Nondeterministic Finite Automata

The Language induced by an NFA

An NFA accepts an input string x iff there is a path from the start state to an accepting state that “spells out” x .

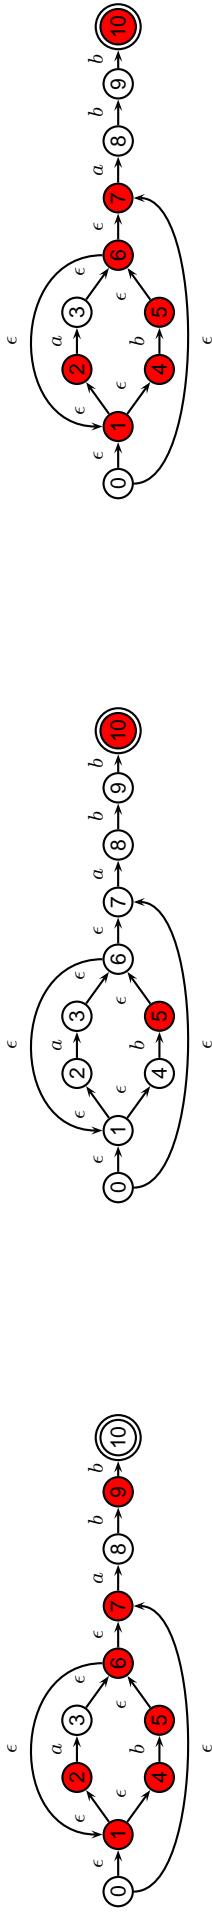

Translating REs into NFAs

Simulating an NFA: $aab \cdot b$, ϵ -closure

Simulating an NFA: $aabb$.

Simulating an NFA: $aabb$, Done

Deterministic Finite Automata

Restricted form of NFAs:

- No state has a transition on ϵ
- For each state s and symbol a , there is at most one edge labeled a leaving s .

Differs subtly from the definition used in COMS V3261
(Sipser, *Introduction to the Theory of Computation*)

Very easy to check acceptance: simulate by maintaining current state. Accept if you end up on an accepting state. Reject if you end on a non-accepting state or if there is no transition from the current state for the next symbol.

Deterministic Finite Automata

Subset construction algorithm

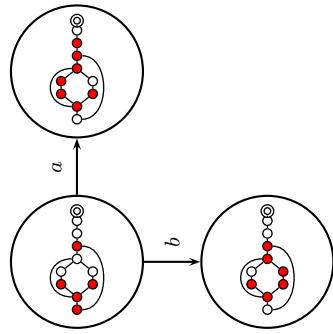

Simulate the NFA for all possible inputs and track the states that appear.

Each unique state during simulation becomes a state in the DFA.

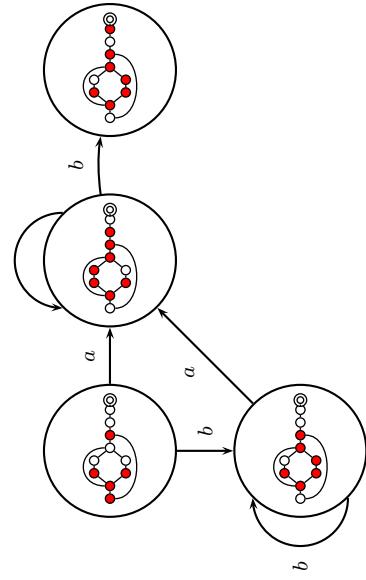

Building a DFA from an NFA

Subset construction algorithm
Simulate the NFA for all possible inputs and track the states that appear.
Each unique state during simulation becomes a state in the DFA.

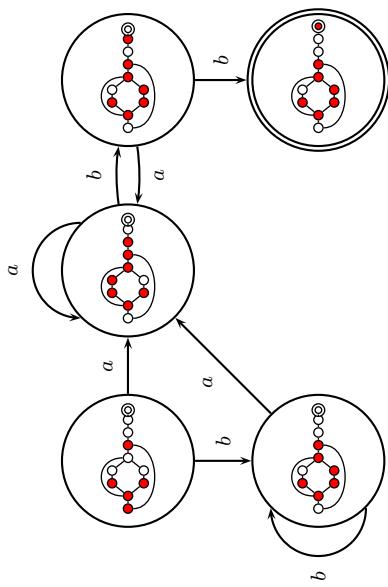

Subset construction for $(a|b)^* abb$ (1)

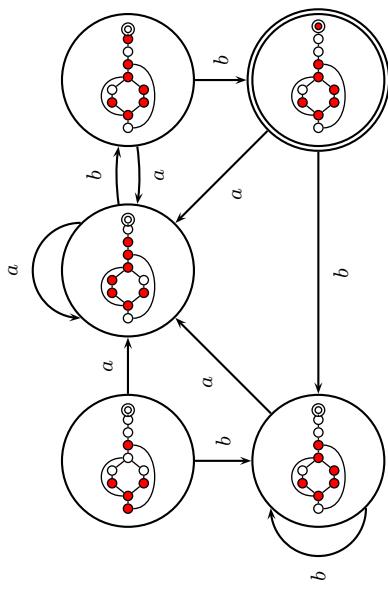

Subset construction for $(a|b)^* abb$ (2)

Subset construction for $(a|b)^*abb$ (3)

Subset construction for $(a|b)^*abb$ (4)

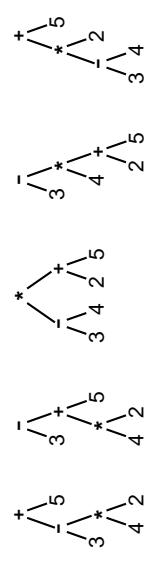

Ambiguous Grammars

A grammar can easily be ambiguous. Consider parsing

$$3 - 4 * 2 + 5$$

with the grammar

$$e \rightarrow e + e \mid e - e \mid e * e \mid e / e$$

Ambiguous: no precedence or associativity.

Fixing Ambiguous Grammars

Original ANTLR grammar specification

```

expr : expr '+' expr
      | expr '-' expr
      | expr '*' expr
      | expr '/' expr
      | NUMBER ;
;
```

Assigning Precedence Levels

Split into multiple rules, one per level

```

term : term '*' term
      | term '/' term
      | atom ;
;
```

Still ambiguous: associativity not defined

Assigning Associativity

Make one side or the other the next level of precedence

```

expr : expr '+' term
      | expr '-' term
      | term ;
;
```

```

term : term '*' atom
      | term '/' atom
      | atom ;
;
```

```

atom : NUMBER ;
```

A Top-Down Parser

```

stmt : 'if' expr 'then' expr
      | 'while' expr 'do' expr
      | expr '==' expr ;
;
```

```

AST Expr() {
    switch (next-token) {
        case "if" : match("if"); expr(); match("then"); expr();
        case "while" : match("while"); expr(); match("do"); expr();
        case NUMBER or ":" : expr(); match(":"); expr();
    }
}
```

Writing LL(k) Grammars

Cannot have left-recursion

```

expr : expr '+' term
      | expr '-' term
      | becomes
      | AST Expr() {
```

```

switch (next-token) {
    case NUMBER : expr(); /* Infinite Recursion */
}
```

Writing LL(1) Grammars

Cannot have common prefixes

```

expr : ID '(' expr ')'
      | ID '=' expr

AST expr() {
    switch (next-token) {
        case ID :match(ID); match('('); expr(); match(')');
        case ID :match(ID); match('='); expr();
    }
}

```

becomes

Eliminating Common Prefixes

Consolidate common prefixes:

$\begin{array}{l} \text{expr} \\ : \text{expr} \text{ '+' term} \\ \text{expr} \text{ '-' term} \\ \text{term} \\ ; \end{array}$	becomes $\begin{array}{l} \text{expr} : \text{term expr} ; \\ \text{expr} : '+' \text{ term expr} \\ '-' \text{ term expr} \\ /* \text{ nothing */ } \\ ; \end{array}$
$\begin{array}{l} \text{expr} \\ : \text{expr} \text{ '+' term} \\ \text{expr} \text{ '-' term} \\ \text{term} \\ ; \end{array}$	becomes $\begin{array}{l} \text{expr} : \text{term expr} ; \\ \text{expr} : '+' \text{ term expr} \\ '-' \text{ term expr} \\ /* \text{ nothing */ } \\ ; \end{array}$

Eliminating Left Recursion

Understand the recursion and add tail rules

```

expr   : expr ('+' term | '-' term )
       | term
       ;
becomes
expr : term exprt ;
exprt : '+' term exprt
      | '-' term exprt
      | /* nothing */
;

```

Bottom-up Parsing

Rightmost Derivation

1 :	$e \rightarrow t + e$
2 :	$e \rightarrow t$
3 :	$t \rightarrow \mathbf{id} * t$
4 :	$t \rightarrow \mathbf{id}$
A rightmost derivation	
	e
	$t + e$
	$t + L$
	$L + \mathbf{id}$
	$\mathbf{id} * L + \mathbf{id}$
	$\mathbf{id} * L + \mathbf{id}$

Basic idea of bottom-up construction this right-to-left.
e
 $t + e$
 $t + t$
 $t + t$

Basic idea of bottom-up parsing:
construct this rightmost derivation
backward.

Each highlighted section is a handle.

Taken in order, the handles build the tree from the leaves to the root.

Shift-reduce Parsing

	stack	input	action
1 :	$e \rightarrow t + e$	Id	shift
2 :	$e \rightarrow t$	Id	shift
3 :	$t \rightarrow \text{Id} * t$	$\text{Id} *$	shift
4 :	$t \rightarrow \text{Id}$	Id	reduce (4)
			reduce (3)
			shift
			shift
			reduce (4)
			reduce (2)
			reduce (1)

e
Scan input left-to-right, looking for handles.
An oracle tells what to do

LR Parsing

The diagram illustrates the state transitions of a parser. The stack starts at state 0 and receives input 'Id'. It moves to state 1 via action 'shift, goto'. The stack then receives input '*' and moves to state 2 via action 'shift, goto'. It receives input 'Id' and moves to state 3 via action 'shift, goto'. Finally, it receives input '*' and moves to state 4 via action 'shift, goto'.

4	5	6	7	2
s1	r3	r3	r3	
5	r3	r3	r3	
6	r1	r1	r1	acc

LR Parsing

				action
1 :	$e \rightarrow t + e$	stack	input	shift, goto
2 :	$e \rightarrow t$	$\boxed{0}$	$* \text{Id} + \text{Id } \$$	shift, goto
3 :	$t \rightarrow \text{Id} * t$	$\boxed{0} \quad \boxed{t}$	$\text{Id} + \text{Id } \$$	shift, goto
4 :	$t \rightarrow \text{Id}$	$\boxed{0} \quad \boxed{t} \quad \boxed{*}$	$\text{Id} + \text{Id } \$$	reduce w/ $\text{Id } \$$
	action	goto		
	$\text{Id} + * \quad \$$	$e \quad t$	Action is reduce with rule 4 $(t \rightarrow \text{Id})$. The right side is removed from the stack to reveal	
0	0 \$	7	2	
1	1 r4 r4 s3 r4			
2	2 r2 s4 r2 r2			
3	3 r2			

4	s ₁				tells us to go to state 5 when we reduce a t:
5	r ₃	r ₃	r ₃		
6	r ₁	r ₁	r ₁		
7			acc	stack	input

LR Parsing

Constructing the SLR Parse Table

Constructing the SLR Parsing Table

	stack	input	action
1 : $e \rightarrow t + e$	$\boxed{}$	$\text{Id} * \text{Id} + \text{Id} \$$	shift, goto 1
2 : $e \rightarrow t$	$\boxed{\text{Id}}$	$* \text{Id} + \text{Id} \$$	shift, goto 3
3 : $t \rightarrow \text{Id} * t$	$\boxed{\text{Id}} \boxed{\text{Id}}$	$\text{Id} + \text{Id} \$$	shift, goto 1
4 : $t \rightarrow \text{Id}$	$\boxed{\text{Id}}$	$\text{Id} + \text{Id} \$$	shift, goto 1
		$e' \rightarrow t + e$	reduce w/ 4
		$e' \rightarrow t + e$	reduce w/ 3
		$e' \rightarrow t + e$	reduce w/ 2
		$e' \rightarrow t + e$	reduce w/ 1
		$e' \rightarrow t + e$	accept

The states are places we could be in a reverse-rightmost derivation. Let's represent such a place with a dot.

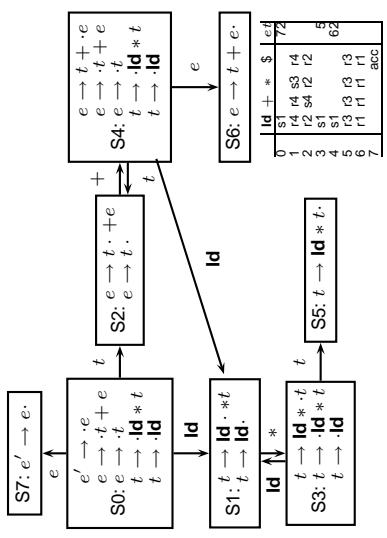

1 : $e \rightarrow t + e$

2 : $e \rightarrow t$

3 : $t \rightarrow \text{Id} * t$

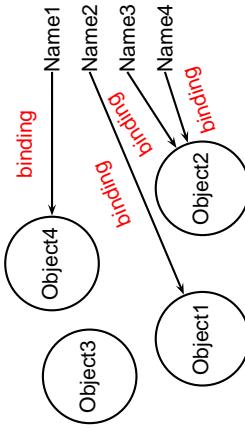

4 : $t \rightarrow \text{Id}$

Say we were at the beginning ($\cdot e$). This corresponds to $e' \rightarrow \cdot e$. The first is a placeholder. The second are the two possibilities when we're just before e . The last two are the two possibilities when we're just before t .

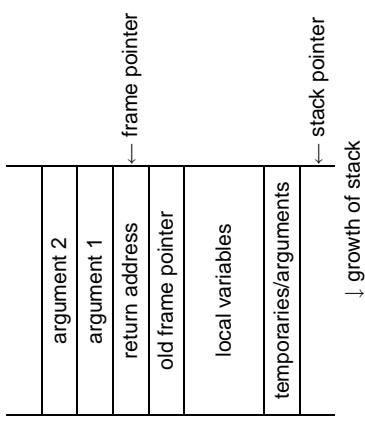

Names, Objects, and Bindings

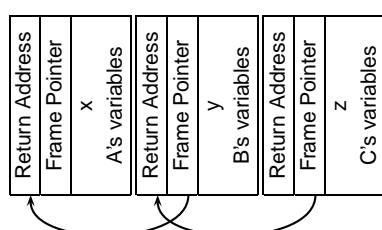

Names, Objects, and Bindings

Symbol Tables in Tiger

Static Semantic Analysis

Static Semantic Analysis

Lexical analysis: Make sure tokens are valid

```
if i 3 "This" /* valid */  
#a1123 /* invalid */
```

Static Semantic Analysis

Syntactic analysis: Makes sure tokens appear in correct order

```
for i := 1 to 5 do 1 + break /* valid */  
if i 3 /* invalid */  
Semantic analysis: Makes sure program is consistent  
let v := 3 in v + 8 end /* valid */  
let v := "f" in v(3) + v end /* invalid */
```

Basic paradigm: recursively check AST nodes.

```
1 + break  
      +  
      / \  
      1 break  
      / \_ 5
```

```
check(+)  
check(1) = int  
check(break) = void  
FAIL: int ≠ void  
Types match, return int
```

Ask yourself: at a particular node type, what must be true?

Implementing multi-way branches

If the cases are *dense*, a branch table is more efficient:

```
switch (s) {  
    case 1: one(); break;  
    case 2: two(); break;  
    case 3: three(); break;  
    case 4: four(); break;  
}  
  
Obvious way:  
if (s == 1) { one(); }  
else if (s == 2) { two(); }  
else if (s == 3) { three(); }  
else if (s == 4) { four(); }  
Reasonable, but we can sometimes do better.
```

Implementing multi-way branches

If the cases are *dense*, a branch table is more efficient:

```
switch (s) {  
    case 1: one(); break;  
    case 2: two(); break;  
    case 3: three(); break;  
    case 4: four(); break;  
}  
  
labels l[] = { L1, L2, L3, L4 }; // Array of labels */  
if (s>=1 && s<=4) goto l[s-1]; // not legal C */  
L1: one(); goto Break;  
L2: two(); goto Break;  
L3: three(); goto Break;  
L4: four(); goto Break;  
Break:
```

Reasonable, but we can sometimes do better.

Applicative- and Normal-Order Evaluation

```
int p(int i) { printf("%d ", i); return i; }  
void q(int a, int b, int c) {}  
{  
    int total = a;  
    printf("%d ", b);  
    total += c;  
}  
q( p(1), 2, p(3) );  
Applicative: arguments evaluated before function is called.  
Result: 1 3 2.  
Normal: arguments evaluated when used.  
Result: 1 2 3
```

Applicative- and Normal-Order Evaluation

```
int p(int i) { printf("%d ", i); return i; }  
int q(int a, int b, int c) {}  
q( p(1), p(2), p(3) );  
Prints 1 2 3.  
Some functional languages also use normal order  
evaluation to avoid doing work. "Lazy Evaluation"  
Will not print 5 6 7. It will print one of  
1 2 3, 1 3 2, 2 1 3, 2 3 1, 3 1 2, 3 2 1
```

Applicative- vs. and Normal-Order

Most languages use applicative order.

Macro-like languages often use normal order.

```
#define P(x) (printf("%d ",x), x)  
#define Q(a,b,c) total = (a), \  
                  printf("%d ", (b)), \  
                  total += (c)
```

```
q( P(1), 2, P(3) );  
Applicative: arguments evaluated before function is called.  
Result: 1 3 2.  
Normal: arguments evaluated when used.  
Result: 1 2 3
```

Nondeterminism

Nondeterminism is not the same as random:

Compiler usually chooses an order when generating code.
Optimization, exact expressions, or run-time values may affect behavior.
Bottom line: don't know what code will do, but often know set of possibilities.

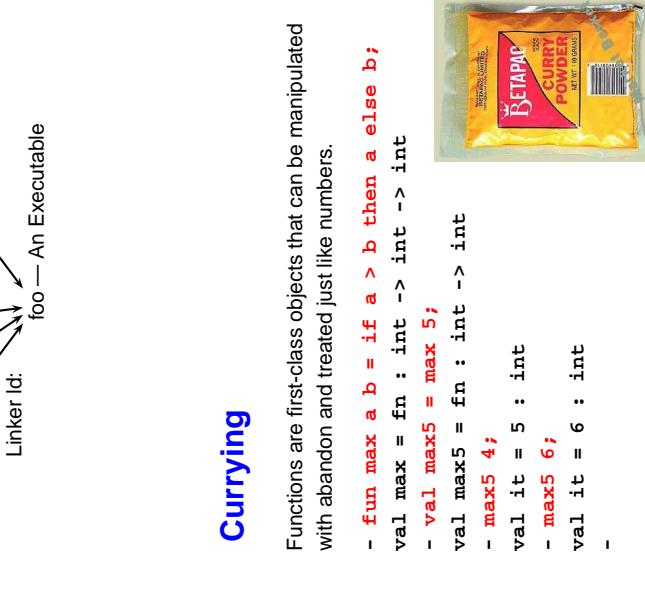

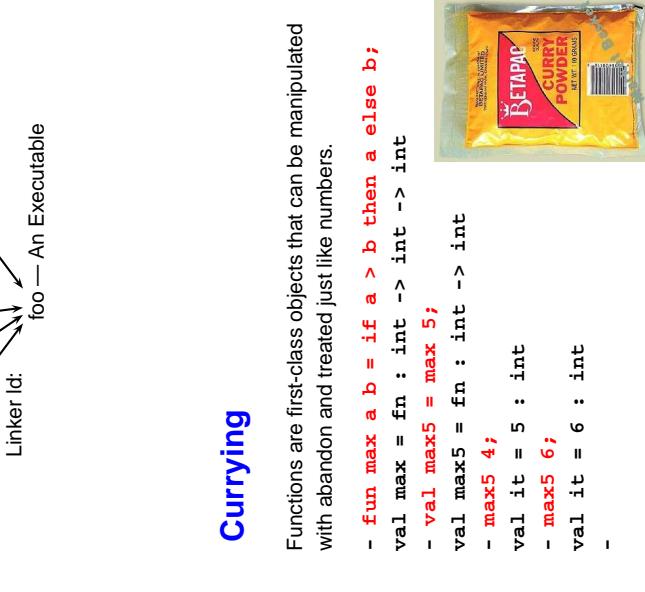

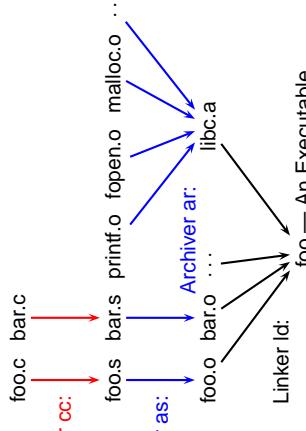

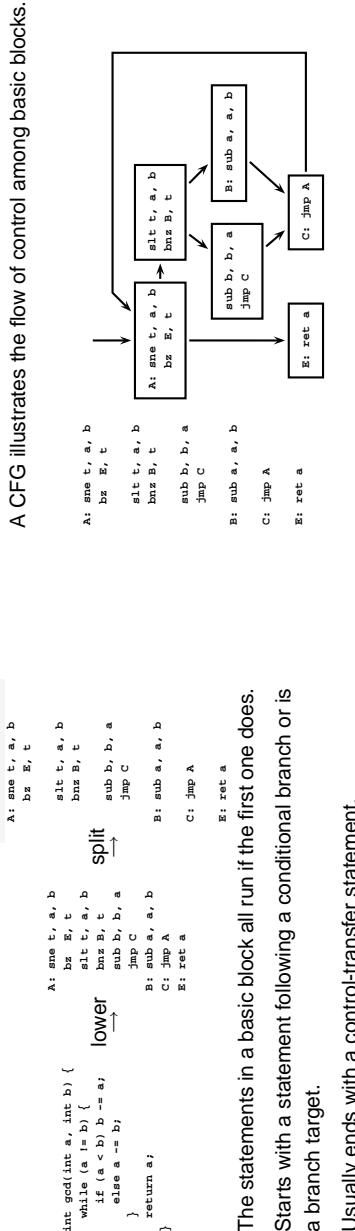

```
int p(int i) { printf("%d ", i); return i; }  
int q(int a, int b, int c) {}  
q( p(1), p(2), p(3) );  
Prints 1 2 3.
```

Basic Blocks

Control-Flow Graphs

Separate Compilation

Simple functional programming in ML

A function that squares numbers:

```

% sml
Standard ML of New Jersey, Version 110.0.7
- fun square x = x * x;
val square = fn : int -> int
- square 5;
val it = 25 : int
-
```

Notice the odd type:
`int -> int -> int`

This is a function that takes a function and returns a function that takes a function and returns an integer.

A more complex function

- fun max a b =
 - = if a > b then a else b;
- val max = fn : int -> int -> int
- max 10 5;
 - val it = 10 : int
- max 5 10;
 - val it = 10 : int
- square 5;
 - val it = 25 : int

Fun with recursion

- ```

- fun addto (l,v) =
 = if null l then nil
 = else hd l + v :: addto(tl l, v);
val addto = fn : ('a -> 'b) * 'a list -> 'b list
-
```
- ```

- addto([1,2,3],2);
val it = [3,4,5] : int list

```

More recursive fun

- ```

- fun map (f, l) =
 = if null l then nil
 = else f (hd l) :: map(f, tl l);
val map = fn : ('a -> 'b) * 'a list -> 'b list
If f is "-", reduce (f,z,a::b::c) is a - (b - (c - z))

```
- ```

- reduce( fn (x,y) => x - y, 0, [1,5]);
val it = ~4 : int

```
- ```

- reduce(fn (x,y) => x - y, 2, [10,2,1]);
val it = 7 : int

```

## Reduce

## Another Example

```
Consider
- fun findl(a,b) =
 = if b then true else (a = 1);
val findl = fn : int * bool -> bool

- reduce(findl, false, [3,3,3]);
val it = false : bool

fn x => fn y => (x + y) * 2;

- reduce(findl, false, [5,1,2]);
val it = true : bool
```

## The Lambda Calculus

Fancy name for rules about how to represent and evaluate expressions with unnamed functions.

Theoretical underpinning of functional languages.

Side-effect free.

Very different from the Turing model of a store with evolving state.

```
ML: The Lambda Calculus:
fn x => 2 * x;
English: "the function of x that returns the product of two and x"
```

## Bound and Unbound Variables

In  $\lambda x. * \ 2\ x$ ,  $x$  is a *bound variable*. Think of it as a formal parameter to a function.

$* \ 2\ x$ " is the *body*.

The body can be any valid lambda expression, including another unnamed function.

```
- $\lambda x. \lambda y. * \ (+\ x\ y)\ 2$
- returns the function of x that returns the function of y that
 returns the product of the sum of x and y and 2."
```

## Grammar of Lambda Expressions

### Calling Lambda Functions

To invoke a Lambda function, we place it in parentheses before its argument.

Thus, calling  $\lambda x. * \ 2\ x$  with 4 is written

 $(\lambda x. * \ 2)\ 4$ 

This means 8.

Curried functions need more parentheses:

 $(\lambda x. (\lambda y. * \ (+\ x\ y)\ 2)\ 4)\ 5$ 

This binds 4 to  $y$ , 5 to  $x$ , and means 18.

### Grammar of Lambda Expressions

Utterly trivial:

|      |   |                           |
|------|---|---------------------------|
| expr | → | constant                  |
|      |   | variable                  |
|      |   | expr expr                 |
|      |   | (expr)                    |
|      |   | $\lambda$ variable . expr |

Somebody asked whether a language needs to have a large syntax to be powerful. Clearly, the answer is a resounding "no."

## Evaluating Lambda Expressions

We need a reduction rule to handle  $\lambda$ s:

```
(\lambda x. * \ 2\ x) 4
(* 2 4)
8
```

This is called  $\beta$ -reduction.  
The formal parameter may be used several times:  
We can reduce either one first. For example:

```
(+ (* 5 6) (* 8 3))
(+ 30 (* 8 3))
(+ 30 24)
```

Looks like deriving a sentence from a grammar.

## Evaluating Lambda Expressions

May have to be repeated:

```
((\lambda x. (\lambda y. -\ x\ y)) 5) 4
(\lambda y. -\ 5\ y) 4
(-\ 5 4)
1
```

Functions may be arguments:

|                    |             |
|--------------------|-------------|
| (λf.f 3)(λx.+ x 1) | (λx.+ x 1)3 |
|                    | (+ 3 1)     |
|                    | 4           |

```
(\lambda f. f 3)(\lambda x. + x 1)
(\lambda x. + x 1)3
(+ 3 1)
4
```

## Normal Form

## Normal Form

A lambda expression that cannot be reduced further is in *normal form*.

Thus,

$\lambda y.y$

is the normal form of

$(\lambda x.\lambda y.y) (\lambda z.z) (\lambda z.z)$

Not everything has a normal form

$(\lambda z.z) (\lambda z.z)$

can only be reduced to itself, so it never produces an non-reducible expression.

“Infinite loop.”
